Without agriculture, there is no stability, without grain, there is chaos.

Deng Xiaoping

Introduction

Several factors make Asian grain production and consumption key to understanding the global balance of grain exports, imports, and food sufficiency. Asia has the world's two most populous countries, China with ~1.2 billion people, and India with ~1 billion and on track to exceed China in population within 20–30 years. Asia is the dominant producer of rice, yet an insignificant amount enters world grain trade. Asia is a major net importer of wheat and soybeans, thus influencing decisions about quality priorities in exporting countries. Asian countries have tended to aim for grain self-sufficiency for reasons of agrarian stability, foreign currency conservation, and independence from political restrictions on their imports from major western producers. Major successes in grain production over recent decades have increased confidence in regional capability to seek continuing technological solutions to create ever-increasing productivity. This confidence has been dented by stalling yield gains, especially in overexploited rice soils, and by industrialization and urbanization, which absorb agricultural land and compete for water resources. This article will discuss these issues, focusing on

three major themes: (1) statistical patterns of grain production, import, and export; (2) the impact and aftermath of the Green Revolution in wheat and rice production; and (3) the role of China as a consuming giant in an era where small-scale grain production makes less economic sense, and where increasing prosperity drives demand for grain-intensive animal product consumption. Asia is a diverse region with many countries of widely differing land area, population, and specific problems. These will not be discussed separately, but the main issues will be presented by discussion of the few of the biggest countries.

The General Problem

Although rice is the staple crop for half the population of the world, only 2% of total production is traded on international markets. The principle of national production for domestic consumption has driven most Asian countries to aim primarily for self-sufficiency (although some countries such as Thailand and India are rice exporters). In many countries, such as Philippines, self-sufficiency is difficult to achieve. Populations are increasing; people are increasingly moving off the land to the cities; water supply is not sufficient to produce the possible three harvests per year on the rice paddies; every flat arable piece of land is already in production, so major land-use changes tend to be those taking land out of production. In the Philippines and elsewhere, rice has in many areas been grown continuously in the same fields for centuries. It had long been supposed that atmospheric and waterborne mineral and trace element additions to the soil are sufficient to allow indefinite maintenance of soil fertility, requiring only macronutrients and water for each new crop. But results of long-term field experiments analyzed at the International Rice Research Institute (IRRI) near Manila showed that across Asia, for irrigated rice systems, the soil base has been depleted of nutrients by continuous monoculture. The result of this is that the same variety responds less to the same level of added nitrogen. In other words, improved varieties and production methods are needed simply to maintain current yield levels. In future, expanded use of hybrid rice varieties using Chinese technology may increase yield per unit area but also further increase mineral depletion and biomass removal from the field. Philippines has achieved approximate self-sufficiency in rice in 2004 but this may be transient; demand will continue to increase, and energy-intensive inputs will still be required. Farmers who produce rice on small pieces (typically 2 ha) of rented land will continue to seek lives with less physical hardship and better incomes elsewhere.

In a 1996 interview, K. Lampe, then Director General of IRRI, summarized the problems of developing tropical Asian economies such as Philippines.

> In 30 years from now we will have for example in the Philippines 120 million people, 60 million more than today. How to feed them nobody seems to care. Over the last 30 years rice has had to increase to such an extent that 600 million people can eat rice today who otherwise would not be able to. Another 30 years and we are predicting a world population of more than 8 billion people. More than half of them will be rice eaters. A prediction from United Nations data is that about 400 million people will move over the next 10 years from rural areas in Asia to the big cities. What will happen is that the belt of poverty around these mega-urban conglomerations will become most probably unbearable. And what we will face is most probably social unrest of unprecedented magnitude. Our task is to grow more rice on less land with less fertilizer, less pesticides, less labor, because producing rice is one of the most tedious tasks for a farmer.

Production Statistics

Using the Food and Agriculture Organization of the United Nations (FAO) definition of “Asia,” the population of Asia has more than doubled in the past 40 years (Figure 1), and is dominated by its two most populous countries (China and India). The population of China is more or less under control, such that India is likely to overtake it as the world’s most populous nation in the not too distant future. The limited land supply (an index of population density) in China is going to be matched across Asia as a whole as the population of the rest of Asia continues to increase (Figure 1). Although the population density of India is greater than China, the supply of arable land is also greater (Figure 2). Widely quoted figures are that China has 22% of the world’s population but only 7% of the world’s arable land. This creates a stark problem – how to feed ~5 billion Asians in 25 years time without increased supply of high-quality land (indeed, with high-quality land continuing to be lost to urbanization and industrialization). Six Asian countries had populations of 100 million or more in 2001 (Figure 2). Their agricultural populations accounted for 43–66% of their total population, except for Japan, which had only 3.6% of its people engaged in agriculture. Japan, as a highly advanced economy which is already committed to food import rather than food self-sufficiency, has substantially different problems from other Asian countries. It focuses on managing the quality and suitability of its imports,

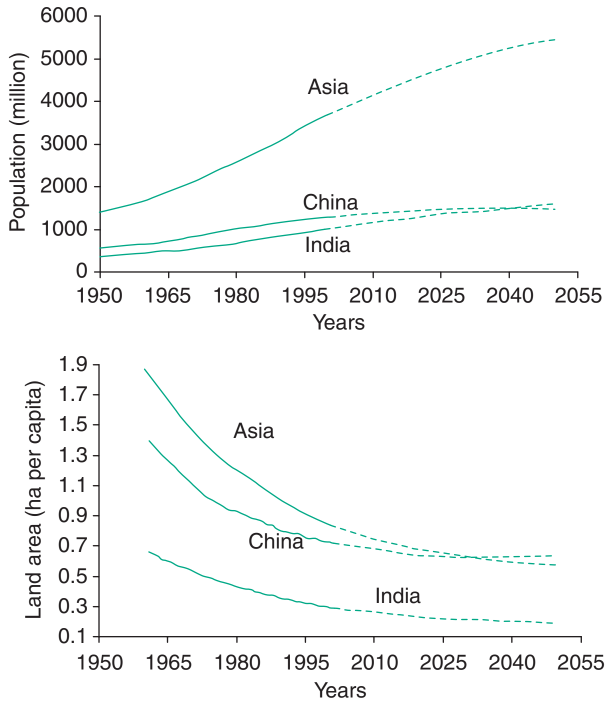

Figure 1 Estimated population (1950–2001) and land area per capita (1961–2000) of all Asia, China, and India, with projections to 2050.

and on maintaining a domestic agricultural sector (e.g., a meat industry using imported grain), which competes poorly on price but which is politically and socially important.

China produces 41% of Asian grain on 26% of the area under cultivation; India produces 22% on 30% of the area (Figure 3). This reflects a wider adoption of intensive cultural practices and some favorable environmental factors in China. Indonesia, another highly populous country, also has greater production per unit area than average for Asia, whereas Thailand shows below-average production. These figures can be used to indicate possible areas for greater technology adoption and hence increased production using existing land under cultivation.

How is Asia's one billion ton (Gt) annual grain production distributed across crops? Asia is well-known for rice production, and for the widespread dietary cultures based on rice consumption. Indeed, more than half of Asian grain production is rice (Table 1, Figure 4) with 523 million ton (Mt) in 2002. Other than for India, Asia is less well known as a wheat producer, yet more than 44% (Table 2) of global wheat production is from Asia, and China is by far the largest wheat producer in the world. Maize production at 166 Mt, again predominantly in China, is substantial. China ranks second to the US in maize production. It is interesting that the center of origin of

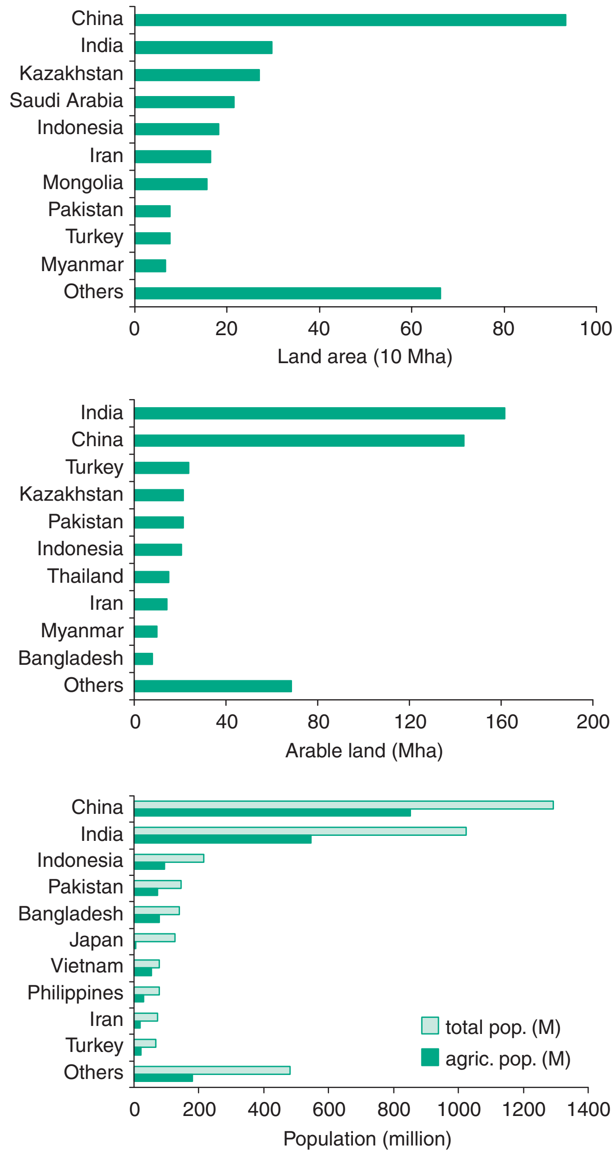

Figure 2 Land area, arable land, and total and agricultural populations of top ten population countries in Asia in 2001. (Data from FAOSTAT Database.)

maize is in America (Mexico) but it has become globally widespread and successful, including in Asia. However, soybean, a crop originating in Asia, is more commercially significant in the US than in Asia. Sorghum and millets are significant crops in arid parts of Asia, typically areas of China and India too dry for maize production. Many local traditional uses of these cereals have developed, for example typical use of sorghum in China is in distilled alcoholic beverage production. Buckwheat also has a significance beyond its relatively small production, with uses in traditional "soba" (Japanese buckwheat noodles) and some Chinese traditional foods such as noodles, vermicelli, and fermented vinegars. Barley is

a substantial crop, fourth after maize, partly reflecting China's rise to rank first in the world for beer production.

Asia's grain imports in 2001 were worth about US$ 25 billion, and exports about $8 billion (Table 2). Imports were dominated by wheat, maize, and soybean, and exports by rice. Industrial, processed food, and feed uses predominate for maize and soybean. The unique properties of wheat flour make it impossible to substitute with any other grain. Strong demand for wheat supplies exists for traditional uses (e.g., noodles and steamed bread in northern China and other temperate Asian countries). Economic development also tends to increase demand for wheat products (e.g., baked bread) at the expense of rice consumption. Thus, many tropical Asian countries that do not produce any wheat require substantial imports (e.g., Philippines, Indonesia, Malaysia). Country data (Table 3) show that Japan is the largest net importer of grain in Asia. Its demand is likely to be stable, due to constant (or slightly declining) population and its advanced economic status (far past the rapid growth stage) and therefore stable dietary patterns. China was a major importer but also a significant exporter (in 2001). But its import–export pattern is highly variable, as slight percentage changes in its large production base, will cause dramatic changes in its import needs and export capacity (Figure 7). India was a net exporter in 2001, and should be able to maintain this capability in the short term. Other countries have adopted a policy that will see sustained dependence on imports, some not having any economic reason or climatic suitability to pursue self-sufficiency (e.g., Saudi Arabia). Sustained import markets are the easiest for exporters to deal with – they can develop relationships with the buyers to understand quality needs and develop long-term policies to meet these needs. Erratic, but large purchases, on international markets are more difficult to handle efficiently.

Total cereal production has risen fairly steadily across Asia as a whole since 1960 (Figure 4) (despite

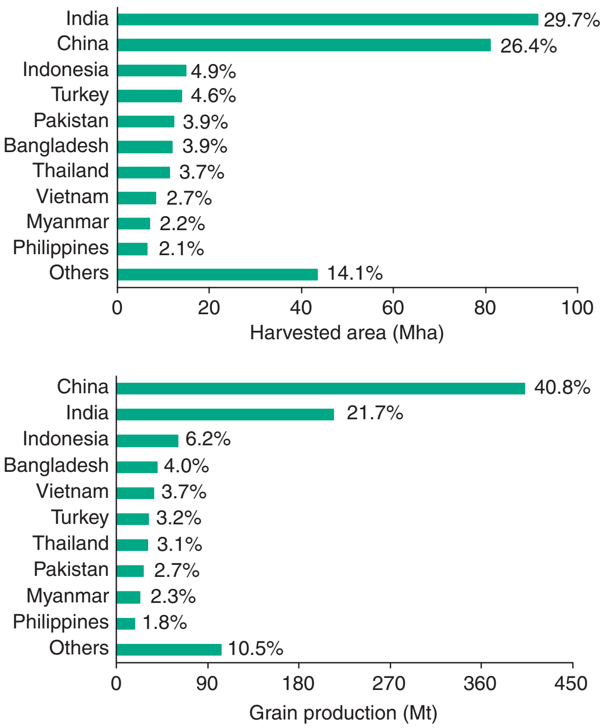

Figure 3 Harvested area and grain production of top ten grain-producing countries in Asia in 2002. Data from FAOSTAT Database. Percentage (%) is based on total harvested area or total grain production in Asia.

Chinese production in the last 5 years, although high, has been more variable than in the past). This reflects improved varieties and agronomic practices (under the Green Revolution, discussed below), but also expansion of cultivated area under the multipronged approaches adopted to cope with vast increases in demand. The situation has become rather less stable in more recent years (Figures 4 and 5), with substantial drops in production of cereal grains other than the big three, namely, rice, wheat, and maize. In fact, between 1992 and 2002 total production (output) increased only ~6%, whereas area harvested

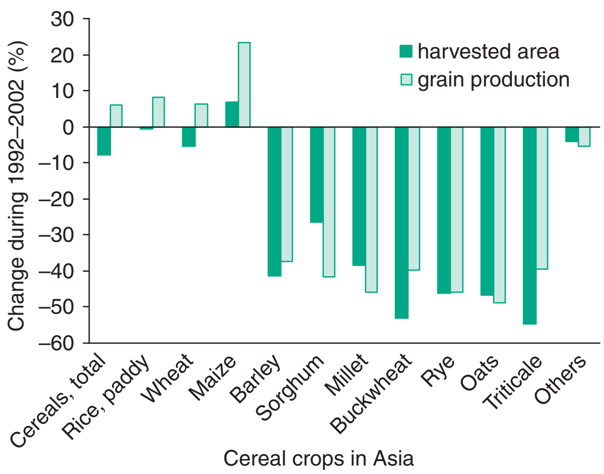

Figure 5 Change in Asian grain production and harvested area of total cereals by crop over the past decade (1992–2002). (Data from FAOSTAT Database.)

decreased ~8%. Although this reflects a healthy improvement in yield per unit area, it underscores worrying trends. One is the diversion of agricultural land to noncereal uses, offering higher returns to farmers, and another is the steady loss of high-quality agricultural land. In many places, such as in parts of China, production of grain on small family-based farm units is no longer economically attractive. Other agricultural activities – vegetables, meat production such as ducks, or even flower production may be preferable. In some cases, land may be left idle while the landholder pursues nonagricultural business activities. These shifts are often beneficial in raising the living standards of rural families. But they also show that more or less open markets, keeping grain prices near world levels, are certainly incompatible with full self-sufficiency in grain.

The Green Revolution

"India has all the food it needs, but half of it is currently being eaten by rats," according to a western aid official quoted in a Financial Times report of December 2002. In the three years up to 2002, India's reserve of rice and wheat increased from 20 to 60 Mt, relative to an annual production of 220 Mt. Half of Indian children are underweight, and many are malnourished. India has seemingly solved one problem – the technological problem for which the solution began with the Green Revolution – only to be left with a perhaps more intractable problem, that of creating an economic system that distributes food equitably and without undue wastage.

Development of dwarf wheat that could sustain high fertilizer inputs and thus produce high grain yields without lodging began at International Center for the Improvement of Maize and Wheat (CIMMYT) in Mexico in the early 1960s. At that time, India's wheat production was low (~10 Mt per year) and static, showing only random seasonal fluctuations from year to year. Like most low-income, high-population countries, population growth was much more rapid than growth in food production, and a social catastrophe seemed imminent. The dwarf wheat from Mexico was introduced to India, through a system of demonstration fields and a supporting package of technology that emphasized to farmers the uniqueness of the new varieties, and the necessity of growing them with the high inputs of water, fertilizer, and other agricultural chemicals. From the mid-1960s, wheat production in India began to increase rapidly, outstripping growth in population – and leading to the present day problem of distribution of excess production. Over a 20-year period (1961–80), overall food production increased 3.6% per year in Asia as

a whole, from 1981 to 2000 (sometimes referred to as "Late Green Revolution"), it increased 2.1% per year. Thus, we should consider the adoption of high-yielding, high-input wheat varieties as the beginning of an agricultural transformation, and not as an abrupt one-time revolution. Present-day technologies may be seen as contributors to the same continuum of progress. If production increases in the range of 2–3% a year, clearly limiting the population growth to less than this is the key to increased production per person.

Shortly after the dwarf wheat varieties came into use, a parallel development started with dwarf rice varieties, distributed from IRRI Philippines. G. S. Khush, the IRRI plant breeder responsible for much of development of these rice varieties, summarized their biological features:

- reduction in plant height (improved harvest index) and higher biomass,
- photoperiod insensitivity (can grow any time of year) and short growth duration (110 days),
- increased yield stability through disease and insect resistance (biotic stresses),
- tolerance to adverse soil conditions (abiotic stresses),
- eating quality, and
- comprehensive agronomic knowledge on crop management, e.g., nutrient requirements, water management, mechanization techniques, and equipment.

These technical inputs alone were not enough. As with wheat in India, production conditions had to be improved. The main factors associated with this are:

- Increased provision of irrigation facilities,
- Availability of inorganic fertilizers, and
- Supportive government policies

The Green Revolution is a high-input system. There is no "free lunch" or nonenergy intensive way to produce such dramatic increases in production. Central to this is farmer knowledge and participation in a system with higher risks (e.g., use of credit to finance the required inputs) but better rewards (higher economic returns).

The Crisis

Grain Supply in China

Chinese tradition and the political leadership have a clear understanding of the importance of grain production, from the proverb "Of all things food is the foremost necessity of the people" to the comment by Deng Xiaoping "Without agriculture, there is no stability, without grain, there is chaos." This has an impact even in relation to Hong Kong: "As long as the overall political situation in China is stable and the economy develops further, we will stand by our agreements and principles agreed with Britain" Qiao Shi (quoted 8 January 1995). This was in relation to the agreed transfer of sovereignty of Hong Kong from the United Kingdom to China from 1997, where substantial autonomy would be granted to Hong Kong (as a "Special Administrative Region") for a period of 50 years. Pragmatically speaking, if a government cannot feed its population, it cannot maintain the credibility to stay in power and carry out its normal obligations. This issue is all the more pressing in China with its large population, limited area of arable land, and recent memory of the disastrous famine of the early 1960s, which caused the deaths of over 30 million people.

Money, Meat, and Grain

The book "Who Will Feed China?" by US environmentalist L. R. Brown, (1995), was perhaps the most influential early study in drawing the attention of western policy-makers to a fairly obvious problem, i.e., grain trade and capacity for global increases in grain production are limited, economic prosperity increases demand, industrialization reduces production, and the huge population of China makes it the key country where these issues converge. Industrialization and urbanization have many effects on agriculture:

1. Loss of agricultural land to urbanization takes out the productive farmland, and of course that nearest to the centers of population;
2. Increased use of motor vehicles – particularly new opportunities for personal ownership of cars, creates need for expanded highway, road, and parking systems, which also absorb agricultural land;
3. Competing demands for water reduces that available for agriculture, and increases the relative cost;
4. Bringing inferior land under cultivation on the peripheries of existing arable land use results in lower average yields, and increased susceptibility to erosion, salinization, and other environmental problems;
5. The movement of people from rural to urban areas in search of better paying jobs reduces agricultural production capacity; and
6. Intensive land use requires ever-greater input of agricultural chemicals and other energy-based inputs, simply to maintain production.

Brown's book had pointed out that "the entire world cannot reasonably aspire to the US standard

of living" and "we cannot afford to keep adding 90 million people a year indefinitely." In food production terms, the difference between the US and other countries is the total per-person demand for grain. Consumption of animal products – with the animals consuming grain-based feed – makes US per capita grain consumption ~800 kg per year. Even Italy, an affluent country with many cultural affinities with the US, has a consumption of only 400 kg per person (and a healthier diet with less obesity). Prediction of China's future grain consumption – currently ~330 kg per person – is the key to preparing to meet future demand. An earlier study "Grain in China" published by the Department of Foreign Affairs and Trade, Australia (1992), had set out in some detail the technical issues related to this. In general, increased prosperity does not lead to large increases in the direct consumption of grain, assuming basic adequacy in dietary energy intake. However, increases in disposable incomes do lead to marked changes in dietary composition, first in the direction of more diversity, and particularly more meat products (and dairy, eggs, fish, etc.). Further increases in incomes will increase consumption of processed foods, meals prepared outside the home, and other convenience options. Taiwan, with a Chinese population of similar dietary customs, can be used as proxy for studying future dietary changes with increased incomes in the Chinese mainland. As mainland China reaches the purchasing-power-adjusted GDP per capita prevailing in Taiwan in the past, the demand for particular food products should also match Taiwan's at that stage of development. Using data up to 1990, Figure 6 shows that an increase in mainland China's GDP per capita from \$1000 to \$2000 would be expected to increase demand for meat by ~10 kg per person per year. Such figures are the basis for concern about China's future needs. An increase in demand from 2003 onwards of a further 10 kg would represent a need for perhaps 40 Mt of grain (depending on feed conversion ratios and the proportion of grain used in the animals' diet). Naturally, one way to proceed is to greatly increase meat imports, with the US and Brazil representing source countries with further potential. However, this, to some extent, just shifts the burden of grain production elsewhere (away from Asia), and would deprive farmers in China of added income if they were simply to produce low-cost commodity grain (at low production efficiency) while imports satisfied needs for higher value products.

For Asia's two biggest countries, we can summarize that China's main driver of demand, for grain, is shifting food consumption patterns (toward meat), whereas India's main driver of demand is increasing population.

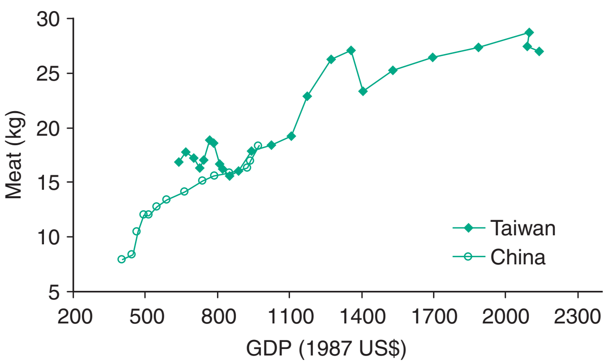

Figure 6 Per capita GDP and meat (pork, beef, and mutton) consumption in China (1977–90) and Taiwan (1952–75). GDP for China is increased threefold to adjust for purchasing power. (Adapted from Garnaut R and Ma G (1992) *Grain in China*, 151pp. Canberra: East Asia Analytical Unit, Department of Foreign Affairs and Trade, Commonwealth of Australia.)

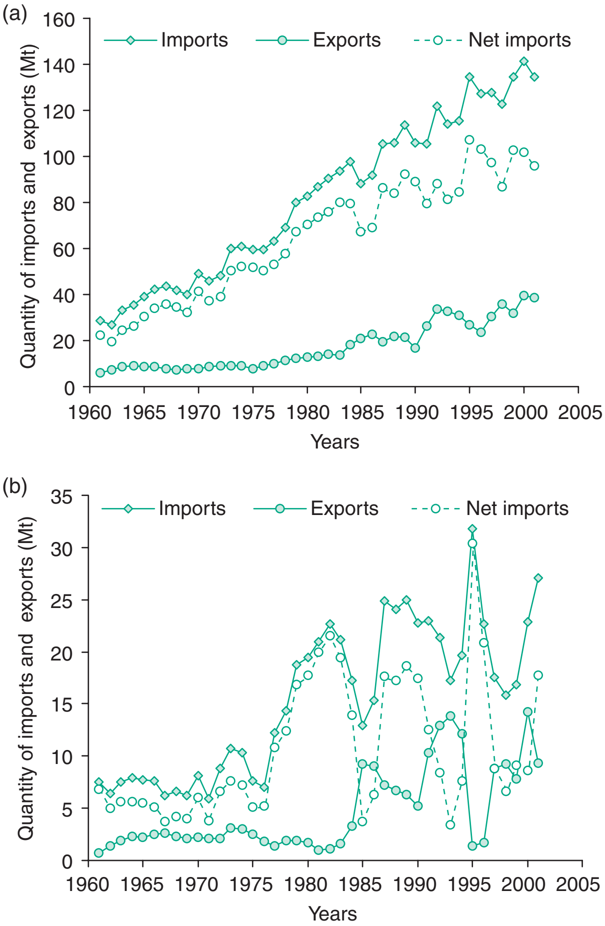

Figure 7 Changes in grain (cereals and soybean) imports and exports in Asia (a) and China (b) from 1961 to 2001.

"Food Price Rises May Herald a World Crisis"

This November 2003 news item published in the *South China Morning Post*, Hong Kong, quoted Lester Brown "Sudden food price rises on the [Chinese] mainland could be the sign of a coming world food crisis. I view these as the warning tremors before the earthquake." Four consecutive years of world grain harvest decline, and historically low world grain stocks since records were kept, could lead to soaring grain prices worldwide. In 2003, wheat prices in northeastern China rose 32%, maize prices by 100%, and rice by 13%. China faced a 40 Mt shortfall in 2003, and the rest of the world, 56 Mt.

In an era of global grain trade (Figure 7) and heightened expectations of diminishing barriers to trade, all consumers (nations) will increasingly compete – on price – for the basic staples necessary for survival. Virtually all major grain producers still use price-distorting mechanisms such as farm subsidies (in some countries, payments not to produce grain; in others, artificially high domestic prices, usually coupled with tariffs and quotas to restrict trade).

"More than just a hill of beans" headed a Washington Post article of November 2003 (published in *The Standard*, Hong Kong). This illustrated the complex relationship among farmer needs, urban consumer needs, and development of grain-processing facilities in producing-yet-importing markets (China) and exporting but price-distorting markets (the US). Recent Chinese restrictions on soybean imports have increased domestic prices, benefiting farmers in Heilongjiang, the main soybean-producing province. Limited supplies of soy meal have increased prices of pork, and soybean oil has also become more expensive, affecting urban shoppers across the country. Rising meat consumption in China has led to development of a soybean feed-processing industry employing 250 000 people. Restricted imports, for whatever reason, affect their livelihoods. China's estimated consumption of soybean is 33 Mt, which is projected to rise to 50 Mt within 5 years; in the face of current production of only ~17 Mt. Expectations of free trade under World Trade Organization (WTO) are commonly undermined by nontariff barriers. Clearly Chinese imports of soybean – from the US – should continue and a mutually beneficial trade will result. The reasons for the restrictions (safety standards for genetically modified soybeans, and phytosanitary regulations concerning phytophthora) obviously have a strong policy overtone. However, they may be placed in context of the widespread demands from developing economy nations for US farm subsidies and tariffs to be reduced in the same spirit of free trade.

General Discussion

Is Biotechnology the Answer?

Biotechnology can provide plant varieties that are more stress-resistant, responsive to appropriate inputs, resistant to pests and diseases (removing the necessity for energy-costly treatments), and are suited to specific end uses. Biotechnology cannot change food production from a "water, dirt, and energy" business into an environmentally stress-free self-sustaining system. Massive increases in food production are needed in the next several decades to keep pace with present demographic trends. Hopefully, population growth will slow and the new plateau in food production will prove to be sustainable. In some ways, biotechnology is distracting governments from the true nature of the problem and from their obligations to act on realistic solutions. Biotechnology has served poorly – if at all – in increasing yields relative to energy inputs. Yield increases over the 40 ongoing years of the Green Revolution have been due to development of varieties that can better sustain such inputs. Limits to population and limits to demand are keys to global food security. Food supply has become too politicized for governments to feel secure placing their fundamental food security in the hands of the most efficient producers. Perhaps the time has come to develop an international treaty guaranteeing free and unimpeded trade in basic foods and medicines, no matter what the prevailing conditions of political conflict or even war between nations.

The Future

Asia is the key to world prosperity, food security, and stability; or the alternative of massive regional famines. Large increases in grain prices will not much affect consumers in the industrialized west. Like oil-price fluctuations, these will be absorbed into the economy. Grain raw material prices are a small percentage of most consumers' monthly food costs in these countries. Most Asian countries will be able to absorb any such structural increases in grain prices – albeit with some economic pain during the readjustment. Most of the poorer Asian countries are more or less self-sufficient in grain, or with increasing prices will have the motivation and capability to become self-sufficient. Rapidly industrializing and developing economies – such as China – will combine continued substantial domestic grain production with the capacity to import additional needs through the strength of their export-focused manufacturing industries. Perhaps long-term grain price increases will enable major producers (in North America and

Europe) to remove farm subsidies and move to more effective free-market production. An additional 100 Mt, for example, of grain entering world trade (at far higher prices than today) will be an attractive prospect to marketing boards and farmers' organizations in the US, Canada, and Australia. But these major exporting countries have to look carefully at the environmental costs of meeting such increased demand. The food supply crisis, although arising from western production constraints and Asian demands, will have its most serious consequences in countries, many in Africa, which have limited production, rapidly rising populations, and few competitive exports. Many of these are the same countries that suffered most in the oil price crises of the past few decades. With grain more than with oil, the impact of the crisis will be more immediate and drastic on the health and survival of the people of these countries.

Europe

M G Lindhauer, Federal Centre for Nutrition and Food, Detmold, Germany

Introduction

In Europe, grain crop production has a long tradition and grains of different plant origin are substantial constituents of the human diet and of animal feed since ancient times.

For the cultivation of grain crops, of cereals especially, Europe has excellent prerequisites because of its climatic and pedological conditions as well as its overall efficient agricultural systems.

Preference for specific grain crops varies very much among European countries and larger geographical regions owing to the wide cultural multiplicity and ethnic diversity in nutritional habits.

Rye may serve as an example. It is not only a cereal very specific to Europe and hardly grown anywhere else in the world, but also within Europe, it is projected as a bread-making cereal as well as animal feed. It is grown almost exclusively in central, northern, and northeastern countries of Europe.

Another point of consideration while recording statistical data is that because the European Union (EU) is politically very diverse, it dominates all the markets including the agricultural one. This is the case, although the EU as yet does not include the accession countries and others like Russia and other countries of the former Soviet Union.

Consequently, data have been prepared and presented with respect to this given political situation but concentrating more on the "mainplayers" to ensure clarity.

Grain Production

Cereals

In Europe, cereals are by far the most important agricultural crops (Tables 1–5), and among these, wheat is the principal crop (Table 1). Wheat accounts for nearly half of the total quantity harvested in 2002.

Table 1 Cereal[a] production in (Mt = millions of metric tons) in Europe in the year 2002

Barley and grain maize and, to a distinctly less degree, rye and oats are also of significance. Triticale, the result of breeding wheat and rye, is in demand in those cultivation areas where normally rye is grown and where farmers are looking for alternatives.

All other cereals are of minor importance. The pseudocereal buckwheat – a plant belonging botanically to the Polygonaceae family – was grown throughout Europe until the early 1900s. It had mostly been grown in areas with poor soils and served for the production of grits and for specific traditional dishes such as pancakes, crêpes, etc. It has survived as a kind of speciality crop, for example, in northern Germany, Russia, and Austria. In very recent years, there has been a certain rekindling of interest in buckwheat as a functional food in modern nutrition systems because of constituents such as dietary fibers which have been scientifically proven to improve health and avoid diseases in human (animal) metabolism.

Rice is produced only in those parts of Europe which have a suitable climate, e.g., Spain, southern France, Italy, or southern Russia.

On the European continent, the EU, with its 15 member countries, is the most important cereal producer accounting for almost half of the production of all the cereals, wheat, barley, maize, triticale, and rice (Table 2).

Among EU member countries, France is the main cereal producer followed by Germany, UK, Spain, and Italy (Table 3). In comparison with the production during the 1990–93 period, in 2003 nearly all the EU members had significantly increased their cereal production, with Greece being the only exception.

The upcoming enlargement of the EU will further strengthen its role as a leading cereal producer (Table 4). Among the accessing countries are respectable cereal producers like Poland, Hungary, and the Czech Republic with the further possibility of countries such as Romania and Turkey joining the EU.

Growing of cereals is a long-standing tradition in the Russian Federation and in the Ukraine, though both countries are yet to utilize their full agronomic capacity, though it must be stated that in both countries there is a strong tendency towards increased harvest quantities (Table 5).

Also, when studying production data for single cereals of Russia, the Ukraine (Table 5), and of those eight countries going to access the EU in 2004 (Table 6), the role of wheat as most preferred cereal is underlined. Barley is in the second position and with rye and oats being in the next position. Yields for cereals as a whole and for individual cereal

varieties given reveal a significantly higher cultivation efficiency within the EU-15 when compared to respective data calculated on the whole-Europe basis. The reasons for this efficient agricultural system are multifold. Without doubt, the average EU-farmer is well educated and experienced and can rely on well-established governmental and private consulting systems. He has unlimited access to production means like fertilizers, pesticides, high-value varieties, and modern technical equipment. Furthermore, the EU has established a closed market with a couple of subsidies and guaranteed threshold prices within an intervention system minimizing farmers' risks and encouraging them to achieve maximum yields. It should also be mentioned that in large parts of the EU climatic and soil conditions are very favorable for cereal cultivation.

Precipitation is rather high and equally distributed throughout the year, temperatures are moderate, being, on an average, not too low during winter for the growth of winter-type cereals (winter wheat, winter rye, etc.). These cereals have a prolonged vegetation period and are thus higher in yield.

Also among EU member countries, yields of different cereals are varying significantly. Data for wheat yield in 2001 (data not shown) may serve as an example. Average yield ranged from 9.06 t ha^{-1} in Ireland to 0.96 t ha^{-1} in Portugal. In countries like Belgium, the Netherlands, Germany, France, Ireland, UK, or Denmark yields much higher than the EU average are standard. To a limited degree, there is also a variation in yield within these countries. These phenomena are the result of differences in climate, soil conditions, utilization of production means, and a question of the choice of varieties among which

there is a broad range in genetically determined yield-forming potential.

Wheat

Additional detailed information on wheat has been provided because of its overall predominance in production and consumption. Data presented in the Tables 1, 2, 5–8 refer to wheat as a single entity. These statistical data do not distinguish between different wheat species. As mentioned above, the so-called soft aestivum wheat (botanical name – *Triticum aestivum*) is the most important wheat species, in Europe and worldwide. Two types of *T. aestivum* wheat are cultivated: winter wheat and spring wheat, where winter wheat is by far the most preferred due to its higher yield performance. Spring-type wheats are chosen when they specifically fit into the crop rotation system or in those countries (e.g., Scandinavia) where climate in winter and the growth period are too uncomfortable for winter-type wheats. In the main wheat-producing countries, the contribution of spring wheat to the total wheat harvest is distinctly less than 1%. *T. aestivum* wheats are covering the wide range of feed and food applications whereas the species *Triticum durum*, known as durum or hard wheat, is specifically grown for pasta production. (This does not mean that pasta production would not be possible from soft wheat, too!)

Durum wheat is more adapted to warmer climatic conditions. Consequently, it is grown in Italy, Spain, France, and Greece where durum wheat cultivation is concentrated within the EU and to a reduced extent in Portugal and Austria (Table 9). In Germany and UK, durum wheat is traditionally not grown but there have been efforts to establish this cereal in regions with suitable climate for reasons of production alternatives for farmers and to supply local durum mills with produce.

In some parts of France, Switzerland, Germany, and Austria, cultivation of spelt wheat (*Triticum spelta*) has been conserved through the centuries for specific use in certain foods and for brewing a special beer. In recent times, people have become more and more conscious of the important role of a healthy nutrition and it is of benefit for health to consume multifold foods and among them those with functional constituents (such as dietary fiber/functional food) and in this context Emmer (*Triticum dicoccon*), small spelt (*Triticum monococcum*), and Kamuth (*Triticum polonicum*) are gaining certain renewed recognition. This is more so in the case of organic farming and its niche clientele. However, the production rates are negligibly low. In addition only baked spelt wheat goods, mainly bread, are available in specialized bakeries.

Rye

Rye is a very important cereal for Europe and – more precisely – for central, east, and northeast European countries and it is hardly grown anywhere else in the world (Tables 1, 2, 5, and 6). This has a historical basis. Rye is assumed to have originated from southwest Asia (Turkey, Iran, Iraq). From there, it is said to have moved to central Europe as a weed along with wheat and barley. But ancient farmers learned to appreciate this "weed" as it turned out to be often more stable and efficient in yield performing than the originally sown cereal, especially on poor sandy soils. Rye has a better drought resistance and efficiency in nutrient uptake from poor substrates.

Consequently, rye was very widely grown in Europe. In some parts, e.g., in UK, it has been replaced again by wheat. But in other parts, it remained of

Table 9 Cultivation area, yield, and production of durum wheat in EU-member countries in 2000 and 2001

EU-15	3706	3758	2.6	2.3	9619	8589

utmost importance in human diet, primarily for bread making.

The most important rye producer is the Russian Federation (Table 5) (the former Soviet Union) followed by Poland (5–6 Mt per year) and Germany (Table 10), which is the most significant rye producer within EU-15. In the Baltic States and in the Nordic countries, rye and rye products are important constituents of human diet and animal feed.

Pulses and Oilseeds

In comparison with cereals, the production of pulses is of lesser importance in Europe (Table 11). It is mainly the EU, the Russian Federation, the Ukraine, and some other east European countries where the production of specific legumes plays a remarkable role. Table 12 provides details of the highest amounts being reported for peas, broad beans, and for some countries, soybeans. Preference for individual species differs very much between countries, depending strongly on traditional diet as far as human consumption is concerned and on recipes of optimized feedstuff mixtures in modern animal production.

This statement is also valid for oilseeds (Tables 11 and 13) among which rapeseed and sunflower are of tremendous significance, whereas other species are speciality crops in specific countries. However, for oilseeds it has also to be stated that they are of lesser importance in relation to cereals although they may contribute to a large extent to agricultural production as in Germany or France, for instance.

Consumption and Utilization

Consumption and utilization of grain seeds in Europe is greatly influenced by factors as varied as climate, soil conditions, preference for specific crops based on tradition and ethnic peculiarities, economics, and governmental regulations. These factors are further compounded by the diversity in regions and countries found on the European continent at large. As it is impossible to discuss every grain species in detail or take into consideration the entire range of diversities, an attempt will be made to focus on major trends and to outline the main fields.

Nearly all grain seeds or components of them serve as food and feed raw materials, and these are by far the most important fields of utilization. Furthermore, these crops or components derived thereof may be used as basic materials for chemical or technical purposes in the nonfood or feed industry. For example, starch is applied for the synthesis of adhesives.

Consumption of Cereals

Taking the EU as an example, it can be shown that this formation as a whole is producing much more cereals than it is able to consume by itself (Table 10). The degree of self supply is more than 100% for soft wheat, rye, and all other cereals. This is specifically valid for the main grain-producing countries like France or Germany. However, there are also countries which lack sufficient production. This means a compensation of surpluses and demands, respectively, within the EU, but it also demonstrates that there is a strong pressure on at least individual countries for export outside the EU or for alternative utilization of cereals.

In 2002, within EU, 193.4 Mt of cereals were consumed, out of which ~120 Mt was used for feed production, and ~45 Mt for food purposes (data not shown). Even after accession of eight new countries in 2004, this general situation will not change very much as they are self-sufficient or even producing surpluses with individual cereals (e.g., rye in Poland). Even if they are not self-sufficient, their consumption market is not very strong due to their restricted number of population.

Countries as Russia, the Ukraine, or Belarus normally do not produce enough cereals to cover their

food and feed needs and only in certain years, the Ukraine acts as a wheat exporter on the world market.

As already mentioned, the largest quantities of cereals are used for feedstuff. Food use is dominated by bread production and the production of other baked goods like pastries, cakes, etc. The significance of this market segment is demonstrated in Table 14 as consumption of flour per capita and year in member countries of the EU and in a few selected non-EU countries.

Flour consumption differs quite a lot between individual countries, within the EU as well as in the others, with the Czech Republic and Romania having extraordinarily high consumption rates.

In the large majority of the European countries the production of bread or comparable foodstuff means production from wheat. This is also true for central, east, and northeastern countries, but here in addition, rye is also used as a raw material for bread making.

The extent to which rye is used is quite different between individual countries. For example, in Germany ~1 Mt of rye are milled for bread production, however this tendency is slowly decreasing.

Bread making does not only mean utilization of pure rye flour. Most breads offered on the market are made of a mixture of rye and wheat flour. In relation to wheat, rye has higher proportions of dietary fibers. Actually, this health benefit is used in arguing in favor of increased rye consumption again.

In countries where rye is traditionally used in human diet, it is also used for feeding of animals. Certain restrictions are related to antinutritive components like pentosans, but this is for young animals only and can be overcome by enzymatic treatment of the raw material.

Rye as well as wheat is used to a certain extent for alcohol production, whereas wheat and maize serve with increasing amounts as raw material for starch production (Tables 15 and 16). These older data from the EU – starch production data are not included in official governmental statistics and therefore hard to obtain – clearly demonstrate the high proportions maize and wheat contribute to total starch manufacturing (Table 15). The reason for increasing utilization of wheat is the production of gluten, which is

a by-product very much in demand in the market for technical purposes and as a flour improver in the baking industry. Table 16 reveals that increasing amounts of starches, i.e., indirectly cereals, are applied for nonfood uses.

In European tradition, maize is of little interest for food use. Minor quantities are used for grits production, as raw material for snacks, while the great majority of grain maize is used in feed.

Because of their β-glucan content with its health benefits, oats are processed to a certain amount to produce special food like flakes, extruded products, etc. But the majority of the production is used for feed.

Consumption of Pulses and Oilseeds

To a limited extent, pulses are used for human consumption, mainly peas, lentils, or different bean varieties. Mostly they are components of feedstuff mixtures.

Table 16 Utilization of starch and starch derivatives in the European Union (EU-15) in selected years

	1995	1998

Oilseeds are mainly used for oil production and the protein-rich residues are feedstuff ingredients. The oil especially that of rapeseed is of high nutritional value and therefore used in increasing amounts for human nutrition. However, the bulk is used for technical applications, the possibilities of applications are being enlarged by special attempts in science and industry under the term renewable resources.

Grain Production in an Expanded EU – An Outlook

The expanded EU will remain one of the main players in the world's grain markets. But this is mainly because of its cereal production and, to a less extent, because of its oilseed production which is mainly growing rape. Pulses will remain of minor interest though there is some effort in the EU to support legume production for feed use to replace imported soybean products.

Among cereals produced wheat will remain the dominant crop. Even in those accessing countries where rye still plays a certain role to date, there will be a shift towards wheat production. In the consumers preferences wheat is accepted as the "more modern" cereal, and it may be assumed that the same development will take place in the rye consumer countries such as the Baltic countries or in Poland as it could be observed in Germany during the 1980s: a movement way from "dark breads" towards "white breads" which means "white breads." This development will be supported by the EU's decision to take rye out of the intervention system starting with 2004.

As it already happend in Germany during 2002, farmers in the rye-producing accession countries will also adapt their rye production to the marked needs and they will replace rye by the growth of wheat and tentatively barley. But barley is also one of the overproduction crops, and by special

regulations the European Commission will try to bring barley prices within the EU (as cereal prices in general) to world market prices.

Attempts of cereal and nutrition scientists to counteract decreasing rye acceptance among people by outlining its specific nutritional benefits will not be very successful. So it may be assumed that rye will become a speciality crop even in Europe.

For wheat it can be outlined an increasing demand of the wet milling industry because, as already mentioned above, vital wheat gluten will remain a competitive by-product of starch production on EU and world markets.

An outlet for cereals in general may be energy production be it as alcohol to be added in certain amounts to gasoline or be it as burning material for specialized power stations. Both kinds of alternative use will be very much dependent on the framework conditions the EU is setting, for example, by tax reduction.

Burning of cereals for energy production is not very popular among European people at the moment. This is a psychological problem as cereals are understood as bread-making and food raw materials.

Another psychological barrier so far in most of the European countries is the use of genetically modified cereals (or crops in general).

To date it can not be foreseen to which extent this breeding tool will increase total grain production or that of "specialized grain species" for very specific applications, e.g., in the chemical industry.

Grain production in the novel EU member countries will soon achieve the standard of most of the previous members with respect to yield and quality. These countries will contribute to a further increase of the surplus in grain production in spite of the growth of the total European population.

An enormous potential for grain, predominantly cereal production, must be stated for the Ukraine and for Russia. But to what extent this potential will become reality will be very much dependent on the respective political conditions offering farmers the necessary stimulus for efficient production.

Cereal Grains in North America

O M Lukow, Agriculture and Agri-Food Canada, Winnipeg, MB, Canada
P B E McVetty, University of Manitoba, Winnipeg, MB, Canada

Introduction

The North American continent is a major production area for grain crops and is a primary or secondary producer in the world of many of the grain crops reviewed in this article. Major grain crops grown in North America include barley, maize, oat, rice, sorghum, and wheat. These major grain crops are grown, to greater or lesser extent, in the countries comprising the North American continent (Canada, USA, and Mexico).

Several of the currently grown major grain crops grown in North America were introduced in the last few centuries, e.g., barley, oat, rice, sorghum, and wheat, whereas maize is native to this continent. All of the current major grain crops in North America have grown from small beginnings to their major field crop status today based on successful research and development in cultivar development, production practices, market development, and new uses development.

This article will review the area used annually to produce each of these major grain crops and their annual production in each North American country and on the continent for a recent and continuous 10-year period. This article will also review the 10-year

mean disposition and consumption of each of these major grain crops in each North American country and on the continent. The percentage of world major grain crop production for each North American country and the ranking of the country, if it is in the top five countries of the world, will be noted. In general, all comments regarding crop disposition and consumption refer to averages since the 1990s, unless specifically stated otherwise. Area and production data for all crops relate to crops harvested for dry grain only. For disposition and consumption of commodities, the definitions of the listed elements are taken from the Food and Agriculture Organization of the United Nations (FAO). Values given for production relate to the total domestic production. Imports cover all movements into the country of the commodity. Stock changes indicate changes in stocks at all levels between the production and retail levels. A negative sign for stock quantities denotes a decrease in supply. Exports cover all movements by the crop commodity out of the country. Domestic supply is defined as: production + imports − exports + changes in stocks. Feed is the amount of the commodity and of edible components of the commodity fed to livestock. Seed comprises the amount of commodity used for reproduction. Waste includes the amount of crop commodity lost in processing, storage, and transportation. Food manufacture is the amount of commodity used for manufacture of processed commodities that cannot be converted back to their originating primary commodities. Food comprises the amounts of the commodity not detailed otherwise in the balance sheet, available for human consumption. Other uses comprise quantities of the commodity used for manufacture of nonfood products.

Barley

Introduction

Barley (*Hordeum vulgare*) is one of the earliest cultivated field crops. It is easily adapted to a wide range of soil and climatic conditions. It occurs in both spring and winter growth habit forms, but it is the spring form that predominates in North American production. Both 2-row and 6-row barley cultivars are grown in North America.

Barley is used in North America primarily for animal feed. A considerable quantity of barley is also malted and used in the beer-brewing industry, while small quantities of barley are used for food (breads, breakfast cereals, and beverages) and planting seed.

Area Harvested

Canada has harvested barley from ~4.3 million hectares (Mha) (8.6% of Canadian arable land) annually (Table 1). The area of barley harvested in Canada has remained nearly constant since the 1990s (Table 1). The vast majority of barley production area in Canada is in the Prairie Provinces (Alberta, Saskatchewan, and Manitoba).

The USA has harvested barley from ~2.4 Mha (1.3% of American arable land) annually (Table 2). The area of barley harvested in the USA has trended down since the 1990s, beginning at almost 3.0 Mha and ending at ~2.0 Mha (Table 2). The vast majority of barley production area in the USA is in the northern and western Plains states.

Mexico is a comparatively small barley producer harvesting barley, from only ~251 000 ha (1.0% of Mexican arable land) annually (Table 3). The area of barley harvested in Mexico has varied widely since the 1990s, from a low of 116 000 ha to a high of 311 000 ha (Table 3). This variation in harvested area is typical for any small volume crop. The majority of barley production area is in central Mexico.

For the entire North American continent, barley was harvested from an average 7.0 Mha (2.7% of North American arable land) annually (Table 4). The area harvested has been fairly consistent every year during 1992–2001 (Table 4). Canada's average barley harvested area was 61.6%, the USA 34.8%, and Mexico less than 3.6% of the North American total barley harvested area.

Production

Canada has produced, on an average, 12.8 million tons (Mt) of barley annually (Table 5). The production of barley in Canada has remained nearly constant since the 1990s (Table 5), paralleling the nearly constant production area for barley harvested in Canada shown in Table 1. The average yield of barley in Canada has been 3.0 t ha^{-1}.

The USA has produced, on an average, 7.7 Mt of barley annually (Table 6). There has been a noticeable decline in the production of barley in the USA since the 1990s, from almost 10 Mt at the beginning of the decade to less than 6 Mt at the end of the decade (Table 6). The average yield of barley in the USA has been 3.2 t ha^{-1}, similar to the Canadian average yield.

Mexico has produced, on an average, 528 000 t of barley annually (Table 7). The production of barley in Mexico has varied widely since the 1990s, from a low of 307 000 t to a high of 762 000 t (Table 7). This variation in production is typical

for any small volume crop. The average yield of barley in Mexico has been $2.1\,t\,ha^{-1}$, a low yield compared to yields for Canada and the USA. Barley is grown in Mexico under water-limiting rain-fed conditions.

For the entire North American continent, average annual barley production was over 21.0 Mt (Table 8). There has been some year-to-year variation in production, but with no clear trend. In terms of North American production proportions, Canada has produced an average 60.8%, the USA 36.7%, and Mexico 2.5% of the barley produced in North America. In global terms, North America has produced, on an average, 14.1% of all the barley produced in the world. The share of world barley production for Canada, USA, and Mexico is 8.6%, 5.2%, and <1.0%, respectively. Canada is in the top five countries of the world for barley production.

Disposition and Consumption

Of the average annual 12.9 Mt of barley produced in Canada and the 24 000 t of barley imported, 9.8 Mt were used domestically and 3.1 Mt were exported (Table 9). Approximately 92% of the barley used domestically in Canada was used for animal feed while small quantities of barley were used for planting seed, food manufacture, food, and other uses (<5%) (Table 9).

Of the average annual 8.2 Mt of barley produced in the USA and the over 902 000 t of barley imported, 7.6 Mt were used domestically and 1.5 Mt were exported (Table 10). Approximately 53% of the barley used domestically in the USA was used for animal feed, while 42% of the barley used domestically was used in food manufacture. Small quantities of barley were used for planting seed and food (<5%) (Table 10).

Of the average annual 510 000 t of barley produced in Mexico and the 284 000 t of barley imported, ~791 000 t were used domestically and 6 t were exported (Table 11). Approximately 35% of the barley used domestically in Mexico was used for animal feed, while 59% of the barley used domestically was used in food manufacture. Small quantities of barley were used for planting seed and food (<5%) (Table 11).

Of the average annual 21.5 Mt of barley produced in North America and 1.2 Mt imported, 18.2 Mt were used domestically and 4.6 Mt were exported (Table 12). Over 73% of the barley used domestically in North America was used for animal feed, while 22% was used for food manufacture. Small quantities were used for planting seed, food, and other uses (<5%) (Table 12).

Maize

Introduction

Maize, (*Zea mays*), is a spring-sown, cross-pollinated annual crop, belonging to the grass family and the tallest of the cereal crops. Early European settlers in North America found maize being cultivated by aboriginal people throughout the continent. Maize is the leading crop in North America and its value is approximately double that of wheat. Maize, along with wheat and rice, is one of the top three cereal crops in the world.

Maize is used in North America primarily for animal feed, while small quantities of maize are used for food manufacture (corn syrup, cornstarch, corn oil) and food (breakfast cereals, tortillas, and alcoholic beverages). Very small quantities of maize are also used for planting seed.

Area Harvested

Canada has harvested maize from ~1.1 Mha (2.2% of Canadian arable land) annually (Table 1). The area of maize harvested in Canada has remained nearly constant since the 1990s (Table 1). The majority of maize production area in Canada is in southern and western Ontario and southwestern Quebec.

The USA has harvested maize from ~28.4 Mha (15.5% of American arable land) annually (Table 2). The area of maize harvested in the USA has remained fairly constant since the 1990s (Table 2). Maize is grown in nearly every state, but the vast majority of maize production area in the USA is in the Middle-American "corn belt" states of Iowa, Illinois, Nebraska, Minnesota, Indiana, Kansas, Wisconsin, and South Dakota.

Maize is a major crop in Mexico. This is reflected in the significant acreage of harvested maize (Table 3). The area of maize harvested in Mexico has remained fairly constant at 7.6 Mha (32.2% of Mexican arable land) annually (Table 3). Maize production occurs throughout Mexico with greater concentration in central Mexico.

For the entire North American continent, maize was harvested from an average 37.1 Mha (14.5% of North American arable land) annually (Table 4). The area harvested has been fairly consistent every year during 1992–2001 (Table 4). Canada's average maize harvested area was 2.9%, the USA 76.6%, and Mexico 20.5% of the North American total maize harvested area.

Production

Canada has produced on an average 7.4 Mt of maize annually (Table 5). The production of maize in

Canada increased in the early 1990s to its present level (Table 5). The average yield of maize in Canada has been $7.0\,t\,ha^{-1}$.

The USA has produced on average 229.4 Mt of maize annually (Table 6). The only times in the past decade that production declined below 200 Mt were in 1993 and 1995 (Table 6). The average yield of maize in the USA has been $8.1\,t\,ha^{-1}$, 15% higher than the Canadian average yield.

Mexico has produced on average 18.1 Mt of maize annually (Table 7). The production of maize in Mexico has steadily increased since the 1990s from a low of 17 Mt in 1992 to a high of more than 20 Mt in 2001 (Table 7). The average yield of maize in Mexico has been $2.4\,t\,ha^{-1}$. The low average yield for maize in Mexico results from the production of mostly unimproved, open pollinated, populations of maize under water-limiting rain-fed conditions.

For the entire North American continent, average annual maize production was over 254.9 Mt (Table 8). There has been some year-to-year variation in production, with a relatively low production year in 1993. In terms of North American production proportions, Canada has produced an average 2.9%, the USA 90.0%, and Mexico 7.1% of the maize produced in North America. In terms of world maize production, North America has produced on an average, 44.7% of all the maize produced in the world. The share of world maize production for Canada, USA, and Mexico is 1.3%, 40.2%, and 3.2%, respectively. The USA is the top maize-producing country in the world. Mexico also ranks in the top five countries of the world for maize production.

Disposition and Consumption

Of the average annual 7.3 Mt of maize produced in Canada and the 1.2 Mt imported, 8.0 Mt were used domestically and over 543 000 t were exported (Table 9). Over 78% of the maize used domestically in Canada was used for animal feed, while 10% of maize was used for food manufacture and 7% for other uses (Table 9). Small quantities of maize were used for planting seed and food (<5%).

Of the average annual 224.3 Mt of maize produced in the USA and the 435 000 t of maize imported, 177.8 Mt were used domestically and 46.6 Mt were exported (Table 10). Approximately 76% of the maize used domestically in the USA was used for animal feed, while 19% of the maize was used in food manufacture. Small quantities of maize were used for planting seed, food, and other uses (<5%) (Table 10).

Of the average annual 17.5 Mt of maize produced in Mexico and the 3.4 Mt of maize imported, over 20.2 Mt were used domestically and 122 000 t were exported (Table 11). Approximately 24% of the maize used domestically in Mexico was used for animal feed, while 58% and 5% of the maize was used in food and food manufacture, respectively. Small quantities of maize were used for planting seed and other uses (< 5%) (Table 11).

Of the average annual 249.1 Mt of maize produced in North America and the 5.0 Mt imported, 206.0 Mt were used domestically and 47.2 Mt were exported (Table 12). Over 71% of the maize used domestically in North America was used for animal feed, while 17% and 8% was used for food manufacture and food, respectively (Table 12). Small quantities of maize were used for seed and other uses (<5%).

Oat

Introduction

Oat, (*Avena sativa*), is a member of the grass family that is grown for cereal grain. It is easily adapted to a wide range of soil and climatic conditions. It occurs in both spring and winter growth habit forms, but it is the spring form that predominates in North America.

Oat is used in North America primarily for animal feed while smaller quantities of oat are used in food (breakfast cereals, bakery products, and snack foods). Very small quantities of oat are used for planting seed (<5%).

Area Harvested

Canada has harvested oat from ~1.4 Mha (2.8% of Canadian arable land) annually (Table 1). The area of oat harvested in Canada has remained nearly constant since the 1990s (Table 1). The vast majority of oat production area in Canada is in the Prairie Provinces (Alberta, Saskatchewan, and Manitoba).

The USA has harvested oat from ~1.2 Mha (0.7% of American arable land) annually (Table 2). The area of oat harvested in the USA has declined since the 1990s, beginning the decade at over 1.8 Mha and ending at ~771 000 ha (Table 2). The majority of oat production area in the USA is in the north central Plains states (Wisconsin, Minnesota, and the Dakotas).

Mexico is a comparatively small oat producer, harvesting oat from only ~45 000 ha (0.2% of Mexican arable land) annually (Table 3). The area

of oat harvested in Mexico has varied widely since the 1990s, from a low of 20 000 ha to a high of 69 000 ha (Table 3). This variation in harvested area is typical for any small volume crop. The majority of oat production area in Mexico is in the northwestern states.

For the entire North American continent, oat was harvested from an average 2.7 Mha (1.0% of North American arable land) annually (Table 4). The area harvested has declined from a high of ~3.0 Mha in the early 1990s to 2.0 Mha in 2001 (Table 4). Canada's average oat harvested area was 52.5%, the USA 45.8%, and Mexico 1.7% of the North American total oat harvested area.

Production

Canada has produced on an average 3.4 Mt of oat annually (Table 5). The production of oat in Canada has remained nearly constant since the 1990s (Table 5). The average yield of oat in Canada has been 2.5 t ha^{-1}.

The USA has produced on an average 2.6 Mt of oat annually (Table 6). There has been a noticeable decline in the production of oat in the USA since the 1990s, from more than 4 Mt at the beginning of the decade to less than 2 Mt at the end of the decade (Table 6). The average yield of oat in the USA has been 2.1 t ha^{-1}, similar to the Canadian average yield.

Mexico has produced on an average 75 000 t of oat annually (Table 7). The production of oat in Mexico has varied widely since the 1990s, from a low of 32 000 t to a high of 121 000 t (Table 7). This variation in production is typical for any small volume crop. The average yield of oat in Mexico since the 1990s has been 1.7 t ha^{-1}, a lower yield compared to that found in Canada and the USA. The lower yield stems from the fact that oat is produced in Mexico under water-limiting rain-fed conditions.

For the entire North American continent, average annual oat production was over 6.1 Mt (Table 8). There has been some year-to-year variation in production, but with no clear trend. In terms of North American production proportions, Canada has produced an average 56.3%, the USA 42.5%, and Mexico 1.2% of the oat produced in North America. In terms of world oat production, North America has produced on an average, 20.5% of the oat produced in the world. The share of world oat production for Canada, USA, and Mexico is 11.5%, 8.7%, and < 1.0%, respectively. Canada and the USA are in the top five countries of the world for oat production.

Disposition and Consumption

Of the average annual 3.4 Mt of oat produced in Canada and the over 9000 t of oat imported, 2.2 Mt were used domestically and 1.2 Mt were exported (Table 9). Over 89% of the oat used domestically in Canada was used for animal feed, while small quantities of oat were used for planting seed (7%) and food (<5%) (Table 9).

Of the average annual 2.8 Mt of oat produced in the USA and the over 1.6 Mt of oat imported, 4.3 Mt were used domestically and 79 000 t were exported (Table 10). Approximately 67% of the oat used domestically in the USA was used for animal feed, while 28% of the oat was used in food. Small quantities of oat were used for planting seed (<5%) (Table 10).

Of the average annual 78 000 t of oat produced in Mexico and the 71 000 t of oat imported in each year, ~149 000 t were used domestically and 43 t were exported (Table 11). Approximately 82% of the oat used domestically in Mexico was used for animal feed, while 16% of the oat used domestically was used in food. Small quantities of oat were used for planting seed (< 5%) (Table 11).

Of the average annual 6.2 Mt of oat produced in North America and 1.7 Mt imported, 6.7 Mt were used domestically and 1.3 Mt were exported (Table 12). Approximately 75% of the oat used domestically in North America was used for animal feed, while 20% was used for food (Table 12). Small quantities were used for planting seed (5%).

Rice

Introduction

Rice, (*Oryza sativa*), is one of the oldest cultivated crops and is the principal food crop of the tropical and subtropical regions of the world. Rice varieties are commonly grouped into three classes according to the shape and length of the grain: long grain, medium grain, and short grain. In North America, only lowland (irrigated) and nonglutinous rice are important commercially.

Rice is used primarily as food with smaller quantities used in food manufacture to produce rice starch and alcoholic beverages. Still smaller quantities of rice are used for seed and other uses (<5%) (Table 10).

Area Harvested

Rice is not grown in Canada. The climate in Canada is unsuitable for rice cultivation.

The USA has harvested rice from ~1.3 Mha (0.7% of American arable land) annually (Table 2).

The area of rice harvested in the USA has remained fairly constant since the 1990s (Table 2). The vast majority of rice production area in the USA is in Arkansas, California, Louisiana, Mississippi, and Texas.

Mexico is a comparatively small rice producer, harvesting rice from only ~84 000 ha (0.4% of arable land) annually (Table 3). The area of rice harvested in Mexico has varied widely since the 1990s, from a low of 53 000 ha to a high of 113 000 ha (Table 3). This variation in harvested area is typical for any small volume crop. Rice is produced in Mexico in the northwestern and central states.

For the entire North American continent, rice was harvested from an average 1.4 Mha (0.5% of North American arable land) annually (Table 4). The area harvested has remained fairly constant (Table 4). The average rice harvest area of the USA and Mexico was 93.8% and 6.2% of the North American total rice harvested area, respectively.

Production

The USA has produced on average 8.4 Mt of rice annually (Table 6). Rice production has been fairly constant (Table 6). The average yield of rice in the USA has been 6.6 $t\,ha^{-1}$.

Mexico has produced on average 372 000 t of rice annually (Table 7). The production of rice in Mexico has remained fairly constant since the 1990s (Table 7). The average yield of rice in Mexico has been 4.4 $t\,ha^{-1}$, a significantly lower yield compared to that found in the USA. Limited crop inputs for rice grown in Mexico reduce average yields.

For the entire North American continent, average annual rice production was 8.8 Mt (Table 8). In terms of North American production proportions, the USA has produced an average 95.8%, and Mexico 4.2% of the rice produced in North America. In terms of world rice production, North America has produced on average, 1.5% of all the rice produced in the world. The share of world rice production for the USA is 1.5%.

Disposition and Consumption

Of the average annual 337 000 t of rice imported into Canada, 321 000 t were used domestically and 16 000 t were exported (Table 9). Over 89% of the rice used domestically in Canada was used for food and 8% was used for other uses (Table 9).

Of the average annual 8.2 Mt of rice produced in the USA and the 488 000 t of rice imported, 5.2 Mt were used domestically and 4.0 Mt were exported (Table 10). Approximately 63% of the rice used domestically in the USA was in food and 14% was used in food manufacture. Small quantities of rice were used for planting seed and other uses (<5%) (Table 10).

Of the average annual 384 000 t of rice produced in Mexico and the 442 000 t of rice imported, ~820 000 t were used domestically and 3 000 t were exported (Table 11). Approximately 85% of the rice used domestically in Mexico was in food and 10% was for food manufacture. Small quantities of rice were used for planting seed and other uses (<5%) (Table 11).

Of the average annual 8.6 Mt of rice produced in North America and the 1.3 Mt imported, 6.3 Mt were used domestically and 4.0 Mt were exported (Table 12). Over 67% of the rice used domestically in North America was used for food and 13% for food manufacture (Table 12). Small quantities of rice were used for planting seed and other uses (<5%). North America is a small rice producer compared to Asia.

Sorghum

Introduction

Sorghum (*Sorghum bicolor*) includes widely diverse types of annual and perennial types. Sorghum grain is the fifth most important cereal in the world. The crop is a heat and drought tolerant, dryland-adapted crop that is generally grown in marginal crop production areas. Sorghum is classified in North America according to its use as a grain sorghum, sweet sorghum, grass sorghum, broomcorn, or special purpose. The statistics presented in this article for sorghum refer only to the grain sorghums.

Sorghum is used in North America primarily as an animal feed. Small quantities are also used for food manufacture (flour) and still smaller quantities of sorghum are used for food (breads, grits, breakfast cereals), other uses (starch), and planting seed.

Area Harvested

Sorghum is not grown in Canada. As in the case of rice, the climate in Canada is unsuitable for grain sorghum production.

The USA has harvested sorghum from ~3.7 Mha (2.0% of American arable land) annually (Table 2). The area of sorghum harvested in the USA has remained fairly constant since the 1990s, although, there were peak years in 1992 and 1996 (Table 2).

The vast majority of sorghum production area in the USA is the southcentral states of Kansas, Oklahoma, Texas, Mississippi, Arkansas, and Louisiana.

Mexico harvested sorghum from ~1.7 Mha (7.0% of Mexican arable land) annually (Table 3). The area of sorghum harvested in Mexico remained constant since the 1990s, except for 1993, where it declined significantly with only 878 000 ha (Table 3). Sorghum production areas in Mexico include the northwestern, northeastern, and central states.

For the entire North American continent, sorghum was harvested from an average 5.4 Mha (2.1% of North American arable land) annually (Table 4). The area harvested had record highs in 1992 and 1996, when there were over 6.0 Mha (Table 4). The average sorghum harvested area for the USA and Mexico was 69.0% and 31.0% of the North American total sorghum harvested area, respectively.

Production

The USA has produced on an average 15.3 Mt of sorghum annually (Table 6). High production years were 1992 and 1996, coinciding with high area harvested years (Table 6). The average yield of sorghum in the USA has been 4.1 t ha^{-1}.

Mexico has produced on an average 5.3 Mt of sorghum annually (Table 7). The lowest production was in 1993 that coincided with low area harvested (Table 7). The average yield of sorghum in Mexico has been 3.2 t ha^{-1}, a significantly lower yield compared to that found in the USA. Sorghum is grown in Mexico under water-limiting rain-fed conditions.

For the entire North American continent, average annual sorghum production was 20.6 Mt annually (Table 8). There has been a significant decline in production since the 1990s, although, there was high production in 1996. In terms of North American production proportions, the USA has produced 74.4% and Mexico 25.6% of the sorghum produced in North America. In terms of global sorghum production, North America has produced on an average, 33.8% of all the sorghum produced in the world. The share of world sorghum production for USA and Mexico is 25.1% and 8.7%, respectively. The USA is in the top five sorghum producers in the world.

Disposition and Consumption

Of the average annual 3000 t of sorghum imported into Canada, 3000 t were used domestically (Table 9). Of the sorghum used domestically in Canada, 100% was used for animal feed (Table 9).

Of the average annual 15.5 Mt of sorghum produced in the USA and the 440 t of sorghum imported, 10.2 Mt were used domestically and 5.9 Mt were exported (Table 10). Approximately 91% of the sorghum used domestically in the USA was used for animal feed, while 5% of the sorghum was used in food manufacture. Small quantities of sorghum were used for food and planting seed (<5%) (Table 10).

Of the average annual 5.1 Mt of sorghum produced in Mexico and the 3.4 Mt of sorghum imported, 8.5 Mt were used domestically and 4000 t were exported (Table 11). Approximately 98% of the sorghum used domestically in Mexico was used for animal feed. Very small quantities of sorghum were used for planting seed (<5%) (Table 11).

Of the average annual 20.6 Mt of sorghum produced in North America and the 3.4 Mt imported, 18.7 Mt were used domestically and 5.9 Mt were exported (Table 12). Over 94% of the sorghum used domestically in North America was used for animal feed (Table 12). Small quantities were used for food manufacture, food, and planting seed (<5%).

Wheat

Introduction

Wheat (*Triticum aestivum, T. durum*) is a member of the grass family that is grown in spring and winter habit forms for cereal grain. It is the most important cereal in the world in terms of production and use for human food and animal feed.

Wheat used in North America is used primarily as food (bread products, pasta, noodles, pastry, breakfast cereals, and baby foods) and for animal feed. Small quantities (<5%) of wheat are also used for other uses (glues, alcohol, and gluten) and planting seed (Table 10).

Area Harvested

Canada has harvested wheat from ~11.4 Mha (22.9% of Canadian arable land) annually (Table 1). The area of wheat harvested in Canada has decreased since the 1990s from a high of 13.9 Mha in 1992 to 10.6 Mha in 2001 (Table 1). The vast majority of wheat production area in Canada is in the Prairie Provinces (Alberta, Saskatchewan, and Manitoba) with minor production in southern Ontario and the Maritimes.

The USA has harvested wheat from ~23.8 Mha (13.0% of American arable land) annually (Table 2). The area of wheat harvested in the USA

has declined since the 1990s, beginning the decade at almost 25.4 Mha and ending at ~19.7 Mha (Table 2). Wheat production area in the USA varies with the class of wheat. Hard red winter wheat is grown in the central and southern Great Plains and the Pacific northwestern states. Hard red spring is grown in the northern Great Plains, soft red winter in the eastern and southeastern states, white in the northeastern states, and in the Great Plains, and durum is grown in the northern Plains states and California.

Mexico is a comparatively small wheat producer, harvesting wheat from only ~809 000 ha (3.4% of Mexican arable land) annually (Table 3). The area of wheat harvested in Mexico has varied widely since the 1990s, from a low of 652 000 ha to a high of 965 000 ha (Table 3). The vast majority of dryland wheat production area in Mexico is in the central region although there is also irrigated wheat production in the northern states.

For the entire North American continent, wheat was harvested from an average 36.0 Mha (14.1% of North American arable land) annually (Table 4). The area harvested has declined from a high of ~40.0 Mha in 1992 to 31.0 Mha in 2001 (Table 4). Canada's average wheat harvested area was 31.7%, the USA 66.1%, and Mexico 2.2% of the North American total wheat harvested area.

Production

Canada has produced on an average 25.7 Mt of wheat annually (Table 5). The production of wheat in Canada has declined noticeably (31%) since the 1990s from a high of 29.9 Mt in 1992 to 20.6 Mt in 2001 (Table 5). The average yield of wheat in Canada has been 2.3 t ha^{-1}.

The USA has produced on an average 63.0 Mt of wheat annually (Table 6). There has been a decline in the production of wheat in the USA since the 1990s, from more than 67.1 Mt at the beginning of the decade to 53.3 Mt at the end of the decade (Table 6). The average yield of wheat in the USA has been 2.6 t ha^{-1}, similar to the Canadian average yield.

Mexico has produced on an average 3.5 Mt of wheat annually (Table 7). The production of wheat in Mexico has remained fairly constant since the 1990s (Table 7). The average yield of wheat in Mexico has been 4.3 t ha^{-1}, a significantly higher yield compared to that found in Canada and the USA. Mexican wheat production is done under irrigation, with high inputs used to produce these high-average grain yields.

For the entire North American continent, average annual wheat production was 92.3 Mt annually (Table 8). There has been a significant decline in production (23%) from 1992 to 2001. In terms of North American production proportions, Canada has produced an average 27.9%, the USA 68.3%, and Mexico 3.8% of the wheat produced in North America. In terms of world wheat production, North America has produced on an average, 16.0% of all the wheat produced in the world. The share of world wheat production for Canada, USA, and Mexico is 4.5%, 11.0%, and < 1.0%, respectively. The USA is in the top five countries of the world for wheat production.

Disposition and Consumption

Of the average annual 26.9 Mt of wheat produced in Canada and the 399 000 t of wheat imported, 7.9 Mt were used domestically and 19.7 Mt were exported (Table 9). Over 52% of the wheat used domestically in Canada was used for animal feed, while 32% were used for food and 14% was used for planting seed. Small quantities of wheat were used for other uses (<5%) (Table 9).

Of the average annual 63.1 Mt of wheat produced in the USA and the 2.7 Mt of wheat imported, 33.6 Mt were used domestically and 32.1 Mt were exported (Table 10). Approximately 70% of the wheat used domestically in the USA was used in food, while 22% of the wheat was used for animal feed and 8% was used for planting seed. Small quantities (<5%) of wheat were used for other uses (Table 10).

Of the average annual 3.6 Mt of wheat produced in Mexico and the 1.9 Mt of wheat imported, ~5.1 Mt were used domestically and 328 000 t were exported (Table 11). Approximately 73% of the wheat used domestically in Mexico was used in food, while 9% was used for animal feed and 8% was for other uses. Small quantities of wheat were used for planting seed (<5%) (Table 11).

Of the average annual 93.5 Mt of wheat produced in North America and 5.0 Mt imported, 46.6 Mt were used domestically and 52.0 Mt were exported (Table 12). Over 64% of the wheat used domestically was used for food, while 26% was used for animal feed and 8% for planting seed (Table 12). Small quantities were used for other uses (<5%).

Oilseeds in North America

P B E McVetty, University of Manitoba, Winnipeg, MB, Canada

O M Lukow, Agriculture and Agri-Food Canada, Winnipeg, MB, Canada

Introduction

The North American continent is a major production area for oilseeds and is a primary or secondary producer in the world of many of the oilseeds reviewed in this article. Major oilseeds grown in North America include linseed, rapeseed, soybean, and sunflower. These oilseeds are grown, to greater or lesser extent, in the countries comprising the North American continent (Canada, the USA, and Mexico).

Several of the major oilseeds currently grown in North America were introduced in the last few centuries (e.g., linseed, rapeseed, and soybean) whereas sunflower is native to this continent. All the current major oilseeds in North America have grown from small beginnings to their major field crop status today based on successful research and development in cultivar development, production practices, market development, and new uses development (*see* **Canola**: Genetics and Breeding; Agronomy; Harvest, Transport, and Storage; Processing. **Soybean**: Germplasm, Breeding, and Genetics; Agronomy; Grading and Marketing; Processing; Soymilk, Tofu, and Okara. **Sunflower**).

This article will review the area used annually to produce each of these major oilseeds and their annual production in each North American country and on the continent for a recent and continuous 10-year period. The 10-year mean disposition and consumption of each of these major oilseeds in each North American country and on the continent will also be reviewed. The percentage of world major oilseed crop production for each North American country and the ranking of the country, if it is in the top five countries of the world, will be noted. In general, all comments regarding crop disposition and consumption refer to averages of the 1990s, unless specifically stated otherwise. Area and production data for all crops relate to crops harvested for dry grain only. For disposition and consumption of commodities, the definitions of the listed elements are taken from the Food and Agriculture Organization (FAO) of the United Nations. Values given for production relate to the total domestic production. Imports cover all movements into the

country of the commodity. Stock changes indicate changes in stocks at all levels between the production and retail levels. A negative sign for stock quantities denotes a decrease in supply. Exports cover all movements by the crop commodity out of the country. Domestic supply is defined as: (production + imports) − (exports + changes in stocks). Feed is the amount of the commodity and of edible components of the commodity fed to livestock. Seed comprises the amount of commodity used for reproduction. Waste includes the amount of crop commodity lost in processing, storage, and transportation. Food manufacture is the amount of commodity used for manufacture of processed commodities that cannot be converted back to their originating primary commodities. Food comprises the amounts of the commodity not detailed otherwise in the balance sheet, available for human consumption. Other uses comprise quantities of the commodity used for manufacture of nonfood products.

Linseed (Flax)

Introduction

Linseed (*Linum usitatissimum*), also known as flax in North America, is one of the earliest cultivated field crops, initially grown for its fiber, but grown, in the last two centuries, for its oil. It is a spring annual adapted to a wide range of soil and climatic conditions in the warm temperate zones of the northern hemisphere.

Linseed in North America is used primarily to produce industrial oil and animal feed meal. Linseed oil is a drying oil used in paints and varnishes and for the manufacture of linoleum flooring. Whole linseed is fed to poultry to produce omega-3 fatty acid enriched eggs. Linseed is also used in food products (breads and breakfast cereals). Small quantities of linseed are used for planting seed.

Area Harvested

Canada has harvested linseed from ~654 000 ha (1.3% of Canadian arable land) annually (Table 1). The area of linseed harvested in Canada has varied widely during the 1990s, from a low of ~253 000 ha to a high of 860 000 ha (Table 1). The vast majority of linseed production area in Canada is in the Prairie Provinces (Alberta, Saskatchewan, and Manitoba).

The USA has harvested linseed from ~110 000 ha (0.06% of American arable land) annually (Table 2). The area of linseed harvested in the USA has varied widely during the 1990s, from a low of ~37 000 ha to a high of 234 000 ha (Table 2). The vast majority of linseed production area in the USA is in the north-central states of North and South Dakota, Minnesota, and Montana.

Linseed is not grown in Mexico. The climate of Mexico is not suitable for the production of linseed.

For the entire North American continent, linseed was harvested from an average 764 000 ha (0.3% of North American arable land) annually (Table 4). The area harvested has varied widely during the 1990s (Table 4). Canada's average linseed harvested area was 85.6% and the USA 14.4% of the total North American linseed harvested area.

Production

Canada has produced on an average 829 000 t of linseed annually (Table 5). The production of linseed in Canada has varied widely during the 1990s, from a low of 337 000 t to a high of 1.1 million tons (Mt) (Table 5), paralleling the widely varying production area for linseed harvested in Canada as shown in Table 1. The average yield of linseed in Canada during the 1990s has been 1.3 t ha^{-1}.

The USA has produced on an average 134 000 t of linseed annually (Table 6). The production of linseed in the USA has varied widely during the 1990s, from a low of 41 000 t to a high of 291 000 t (Table 6), paralleling the widely varying production area for linseed harvested in the USA shown in Table 2. The average yield of linseed in the USA has been 1.2 t ha^{-1}, similar to the Canadian average yield.

For the entire North American continent, average annual linseed production was 963 000 t annually (Table 8). There has been a threefold variation in year-to-year production of linseed, with a trend towards increased production in recent years. In terms of North American production proportions, Canada has produced an average 86.1% and the USA 13.9% of the linseed produced in North America. In terms of global linseed production, North America has produced on an average, 40.4% of all the linseed produced in the world. The share of world linseed production for Canada and the USA is 34.8% and 5.6%, respectively. Canada is the top linseed producer in the world and the USA ranks in the top five countries in the world for linseed production.

Disposition and Consumption

Of the average annual 812 000 t of linseed produced in Canada and the 13 000 t imported, 178 000 t were

used domestically and 675 000 t were exported (Table 9). Of the linseed used domestically in Canada, 74% was used for food manufacture and other uses combined (seed crushed for industrial oil and meal production for feed), and 17% was used for planting seed (Table 9). Small amounts of linseed (<5%) were used for food. Canada is a major exporter of linseed to the world (675 000 t), with significant exports to Europe, the USA, Japan, and South Korea. Canada currently supplies nearly 60% of the linseed used in the USA.

Of the average annual 113 000 t of linseed produced in the USA and the over 170 000 t of linseed imported, 279 000 t were used domestically and 4000 t were exported (Table 10). Approximately 96% of the linseed used domestically in the USA was used for food manufacture and other uses combined. Small quantities of linseed were used for planting seed and food (<5%) (Table 10).

The average 1000 t of linseed imported into Mexico were used domestically (Table 11). All of the domestically used linseed in Mexico was used for food manufacture and other uses combined.

Of the average annual 925 000 t of linseed produced in North America and the 184 000 t imported, 458 000 t were used domestically and 679 000 t were exported (Table 12). Approximately 88% of the linseed used domestically in North America was used for food manufacture and other uses combined (Table 12). Small quantities were used for planting seed (7%) and food (< 5%).

Rapeseed (Canola)

Introduction

Rapeseed (*Brassica napus* and *B. rapa*) was domesticated as an oilseed crop in Europe in the early Middle Ages. Because of their ability to germinate and grow at low temperatures, the oilseed *Brassicas* are one of the few oil crops that can be grown in the temperate regions of the world. There are both spring and winter growth habit forms, but it is the spring form that predominates in North American production. The oil and meal quality of rapeseed has been dramatically improved in recent decades and a new name for this quality improved form of rapeseed, "canola," has been widely adopted in most of the world. The phrase "canola-quality rapeseed" will be used for this crop.

Canola-quality rapeseed is primarily used to produce edible vegetable oil and meal for animal feed. Small quantities of canola-quality rapeseed are used directly for feed and planting seed.

Area Harvested

Canada has harvested canola-quality rapeseed from ~4.6 million hectares (Mha) (9.2% of Canadian arable land) annually (Table 1). The area of canola-quality rapeseed harvested in Canada has remained fairly constant during the 1990s (Table 1). The vast majority of canola-quality rapeseed production area in Canada is in the Prairie Provinces (Alberta, Saskatchewan, and Manitoba).

The USA has harvested canola-quality rapeseed from ~293 000 ha (0.2% of American arable land) annually (Table 2). The area of canola-quality rapeseed harvested in the USA has increased more than tenfold during the 1990s, beginning the decade at 53 000 ha and ending at 590 000 ha (Table 2). The vast majority of canola-quality rapeseed production area in the USA is in the northern Plains States (Minnesota and the Dakotas).

Mexico is a very small canola-quality rapeseed producer harvesting canola-quality rapeseed from only 3000 ha (0.1% of Mexican arable land) annually (Table 3). The area of canola-quality rapeseed harvested in Mexico has varied widely during the 1990s, from a low of 549 ha to a high of 10 000 ha, with a trend towards increased harvested area (Table 3). This variation in harvested area is typical for any small volume crop. The vast majority of canola-quality rapeseed production area in Mexico is in the central area of the country.

For the entire North American continent, canola-quality rapeseed was harvested from an average 4.9 Mha (1.9% of North American arable land) annually during the 1990s (Table 4). The area harvested has varied by a factor of 2 during the 1990s, from a low of 3.1 Mha to a high of 6.0 Mha (Table 4). Canada's average canola-quality rapeseed harvested area was 94.0%, the USA 6.0%, and Mexico <1.0% of the total North American canola-quality rapeseed harvested area.

Production

Canada has produced on an average 6.3 Mt of canola-quality rapeseed annually (Table 5). The production of canola-quality rapeseed in Canada has varied by a factor of 2 during the 1990s (Table 5), paralleling the variation in harvested area for canola-quality rapeseed in Canada shown in Table 1. The average yield of canola-quality rapeseed in Canada has been 1.4 t ha^{-1}.

The USA has produced on an average 443 000 t of canola-quality rapeseed annually (Table 6). Canola-quality rapeseed production has increased by more than tenfold in the USA, from under 72 000 t at the beginning of the 1990s to over 908 000 t at the end

of the 1990s (Table 6). The average yield of canola-quality rapeseed in the USA has been $1.5\,t\,ha^{-1}$, similar to the Canadian average yield.

Mexico has produced on an average 4000 t of canola-quality rapeseed annually (Table 7). The production of canola-quality rapeseed in Mexico has varied by a factor of almost 30 during the 1990s, from a low of 505 t to a high of 14 000 t (Table 7). This variation in production is typical for any small volume crop. The average yield of canola-quality rapeseed in Mexico has been $1.3\,t\,ha^{-1}$, similar to yields for Canada and the USA.

For the entire North American continent, average annual canola-quality rapeseed production was 6.8 Mt (Table 8). There has been year-to-year variation in production, with a trend towards increased production, mostly in the USA, in recent years. In terms of North American production proportions, Canada has produced an average 93.4%, the USA 6.6%, and Mexico <1.0% of the canola-quality rapeseed produced in North America. In terms of global canola-quality rapeseed production, North America has produced on an average, 20.1% of all the canola-quality rapeseed produced in the world. The share of world canola-quality rapeseed for Canada, the USA, and Mexico is 18.8%, 1.3%, and <1.0%, respectively. Canada ranks in the top five countries of the world for canola-quality rapeseed production.

Disposition and Consumption

Of the average annual 6.2 Mt of canola-quality rapeseed produced in Canada and the 106 000 t imported, 3.1 Mt was used domestically and 3.2 Mt was exported (Table 9). Over 86% of the canola-quality rapeseed used domestically in Canada was used for food manufacture, 6% for feed, and small amounts were used for planting seed (<5%) (Table 9).

Of the average annual 307 000 t of canola-quality rapeseed produced in the USA and the 292 000 t of canola-quality rapeseed imported in each year of the 1990s, 477 000 t were used domestically and 122 000 t were exported (Table 10). Approximately 88% of the canola-quality rapeseed used domestically in the USA was used for food manufacture, and 8% for other uses (Table 10). Small amounts were used for planting seed (<5%).

Of the average annual 3000 t of canola-quality rapeseed produced in Mexico and the 583 000 t of canola-quality rapeseed imported, ~586 000 t were used domestically and 90 t were exported (Table 11). Approximately 95% of the canola-quality rapeseed used domestically in Mexico was used for food manufacture with amounts used for planting seed (<5%) (Table 11).

Of the average 6.5 Mt of canola-quality rapeseed produced in North America and the 981 000 t imported, 4.1 Mt were used domestically and 3.3 Mt were exported (Table 12). Over 88% of the canola-quality rapeseed used domestically in North America was used for food manufacture (Table 12). Small amounts were used for feed, planting seed, and other uses (<5%).

Soybean

Introduction

Soybean, (*Glycine max*), was domesticated as a forage crop in China ~2500 BC. It became a commercially viable oilseed crop in the 1940s due to the development of shatter and disease-resistant new cultivars. There are only spring growth habit forms. Soybeans are grown widely throughout the world for their high-protein meal and oil.

Soybean is used primarily for food manufacture (edible vegetable oil and meal for animal feed) (Table 9). Small quantities of soybeans are also used directly as animal feed, food ("tofu" and soy sauce), and planting seed.

Area Harvested

Canada has harvested soybean from ~902 000 ha (1.8% of Canadian arable land) annually (Table 1). The area of soybean harvested in Canada has varied by a factor of 2 during the 1990s, from ~623 000 ha to over 1.1 Mha (Table 1). The majority of soybean production area in Canada is in southwestern Ontario.

The USA has harvested soybean from ~26.7 Mha (14.6% of American arable land) annually (Table 2). The area of soybean harvested in the USA has increased during the 1990s, beginning the decade at 23.6 Mha and ending at ~29.5 Mha (Table 2). The vast majority of soybean production area in the USA is in the Middle American "corn belt" states of Iowa, Illinois, Nebraska, Minnesota, Indiana, Kansas, Wisconsin, and South Dakota and the lower Mississippi Delta.

Mexico is a very small soybean producer, harvesting soybean from only 147 000 ha (0.6% of Mexican arable land) annually (Table 3). The area of soybean harvested in Mexico has varied widely during the 1990s, from a low of 49 000 ha to a high of 323 000 ha, with a trend towards decreased harvested area during the 1990s (Table 3). This variation in harvested area is typical for any small volume crop. Soybean production occurs in central Mexico.

For the entire North American continent, soybean was harvested from an average 27.7 Mha (10.8% of North American arable land) annually (Table 4). The area harvested has varied slightly, from a low of 24.0 Mha to a high of 30.7 Mha (Table 4). Canada's average soybean harvested area was 3.3%, the USA 96.2%, and Mexico <1.0% of the North American harvested area.

Production

Canada has produced on an average 2.3 Mt of soybean annually (Table 5). The production of soybean in Canada has varied by a factor of 2 during the 1990s (Table 5), paralleling the variation in harvested area for soybean in Canada shown in Table 1. The average yield of soybean in Canada has been 2.5 t ha^{-1}.

The USA has produced on an average 67.7 Mt of soybean annually (Table 6). Soybean production has increased by more than 30% in the USA during the 1990s, from 59.6 Mt at the beginning of the 1990s to 78.7 Mt at the end of the 1990s (Table 6). The average yield of soybean in the USA has been 2.5 t ha^{-1}, similar to the Canadian average yield.

Mexico has produced on an average 255 000 t of soybean annually (Table 7). The production of soybean in Mexico has varied by a factor of 10 during the 1990s, from a low of 56 000 t to a high of 594 000 t (Table 7). This variation in production is typical for any medium volume crop. The average yield of soybean in Mexico during the 1990s has been 1.7 t ha^{-1}, lower than the soybean yields seen for Canada and the USA. Soybeans are grown in Mexico under water limiting rain-fed conditions.

For the entire North American continent, average annual soybean production was 70.2 Mt (Table 8). There has been an year-to-year variation in production, with a trend towards increased production, mostly in the USA, in recent years. In terms of North American production proportions, Canada has produced an average 3.2%, the USA 96.4%, and Mexico <1.0% of the soybean produced in North America. In terms of global soybean production, North America has produced on an average, 49.3% of the soybean produced in the world. The share of world soybean production for Canada, the USA, and Mexico is 1.6%, 47.5%, and <1.0%, respectively. The USA is the top soybean producer of the world.

Disposition and Consumption

Of the average annual 2.2 Mt of soybean produced and 188 000 t imported by Canada, 1.8 Mt was used domestically and 554 000 t was exported (Table 9). Almost 75% of the soybean used domestically in Canada was used for food manufacture (Table 9). Another 20% of the soybean domestic supply was used as animal feed. Minor amounts were used for planting seed and food (<5%).

Of the average annual 65.2 Mt of soybean produced in the USA and the 151 000 t of soybean imported, 43.1 Mt were used domestically and 22.1 Mt were exported (Table 10). Approximately 88% of the soybean used domestically in the USA was used for food manufacture (Table 10). Small amounts were used for feed, planting seed, and food (<5%).

Of the average annual 315 000 t of soybean produced in Mexico and the 2.9 Mt of soybean imported, ~3.2 Mt were used domestically and 676 t were exported (Table 11). Approximately 77% of the soybean used domestically in Mexico was used for food manufacture (Table 11). Another 14% of the soybean domestic supply was used as animal feed and 6% was used in other uses. Minor amounts were used for planting seed and food (<5%).

Of the average annual 67.8 Mt of soybean produced in North America and the 3.2 Mt imported, 48.1 Mt were used domestically, 22.7 Mt were exported (Table 12). Over 86% of the soybean used domestically in North America was used for food manufacture (Table 12). Small amounts were used for feed, seed, food, and other uses (<5%).

Sunflower

Introduction

Sunflower, (*Helianthus annuus*), was domesticated as a food crop in North America, perhaps as early as 3000 BC. Sunflower was introduced to Europe in the 1600s and was successfully developed as an oil crop in Russia in the early 1800s. Russian plant breeders were able to increase the oil content in sunflower seed from less than 30% to over 50%, the major factor permitting the development of sunflower as an oil crop for the temperate areas of the world.

Sunflower is used primarily for food manufacture (edible vegetable oil and meal for animal feed) (Table 10). Moderate quantities of sunflower are used for animal feed and food (confectionary and bakery products) (Table 10). Small amounts are used for planting seed (<5%).

Area Harvested

Canada has harvested sunflower from ~62 000 ha (0.1% of Canadian arable land) annually (Table 1).

The area of sunflower harvested in Canada has varied by a factor of 2 during the 1990s, from a low of 35 000 ha to a high of 83 000 ha (Table 1). The vast majority of sunflower production area in Canada is in the Prairie Province of Manitoba.

The USA has harvested sunflower from ~1.2 Mha (0.6% of American arable land) annually (Table 2). The area of sunflower harvested in the USA has remained fairly constant during the 1990s (Table 2). The vast majority of sunflower production area in the USA is in the central Plains States (from Texas to the Dakotas, with North Dakota being the predominant production area State).

Mexico is a minor producer of sunflower, harvesting sunflower from only 968 ha (0.004% of Mexican arable land) annually (Table 3). The area of sunflower harvested in Mexico has varied widely during the 1990s, from a low of 100 ha to a high of 3000 ha, with no apparent trend (Table 3). This variation in harvested area is typical for any small volume crop. The greater part of the sunflower production area is in central Mexico.

For the entire North American continent, sunflower was harvested from an average 1.2 Mha (0.5% of North American land) annually (Table 4). The area harvested has varied by 40% during the 1990s, from a low of 878 000 ha to a high of 1.5 Mha (Table 4). The average sunflower harvested area for Canada, the USA, and Mexico was 5.1%, 94.8%, and <1.0% of the total North American sunflower harvested area, respectively.

Production

Canada has produced on an average 90 000 t of sunflower annually (Table 5). The production of sunflower in Canada has varied by a factor of 2 during the 1990s (Table 5), paralleling the variation in harvested area for sunflower in Canada shown in Table 1. The average yield of sunflower in Canada has been 1.4 t ha^{-1}.

The USA has produced on an average 1.7 Mt of sunflower annually (Table 6). Sunflower production has varied by a factor of 2 in the USA during the 1990s, from ~1.2 Mt to over 2.4 Mt (Table 6). There is no clear trend of production, however. The average yield of sunflower in the USA has been 1.5 t ha^{-1}, similar to the Canadian average yield.

Mexico has produced on an average 933 t of sunflower annually (Table 7). The production of sunflower in Mexico has varied by a factor of 35 during the 1990s, from a low of 70 t to a high of over 2000 t (Table 7). This variation in production is typical for any small volume crop. The average yield of sunflower in Mexico has been 1.0 t ha^{-1}, lower than the yields for Canada and the USA. Sunflower is produced in Mexico under water limiting rain-fed conditions.

For the entire North American continent, average annual sunflower production was 1.8 Mt (Table 8). There has been wide year-to-year variations in production, with no clear trend emerging in production. In terms of North American production proportions, Canada has produced an average 5.0%, the USA 94.9%, and Mexico <1.0% of the sunflower produced in North America. In terms of world sunflower production, North America has produced on an average, 7.6%, of all the sunflowers produced in the world. Canada's and Mexico's share of world sunflower production is <1.0% while the USA share of world sunflower production is 7.2%. The USA is in the top five countries in the world for sunflower production.

Disposition and Consumption

Of the average annual 93 000 t of sunflower produced in Canada and the 16 000 t of sunflowers imported, 62 000 t were used domestically and 50 000 t were exported (Table 9). Over 76% of the sunflowers used domestically in Canada was utilized for food manufacture (Table 9). Another 22% was used directly as animal feed and a small amount was used as planting seed (<5%) (Table 9).

Of the average annual 1.7 Mt of sunflower produced in the USA and the 40 000 t of sunflower imported, 1.6 Mt were used domestically and 170 000 t were exported (Table 10). Approximately 62% of the sunflower used domestically in the USA was utilized for food manufacture (Table 10). Another 21% was used directly as animal feed and 16% as food (Table 10). A small amount was used for planting seed (<5%).

Of the average annual 879 t of sunflower produced in Mexico and the 99 000 t of sunflower imported, ~102 000 t were used domestically and 105 t were exported (Table 11). Approximately 96% of the sunflower used domestically in Mexico was used for food manufacture and a small amount was used for food (<5%) (Table 11).

Of the average annual 1.8 Mt of sunflower produced in North America and the 155 000 t imported, 1.7 Mt were used domestically and 221 000 t were exported (Table 12). Over 64% of the sunflower used domestically in North America was used for food manufacture (Table 12). Another 20% was used directly as animal feed and 15% as food (Table 12). A small amount was used for planting seed (<5%).

Oceania

C Wrigley, Food Science Australia and Wheat CRC, North Ryde, NSW, Australia

Introduction

None of the grains of economic significance are native to the Oceania region (Australia, New Zealand, and the islands of the southern Pacific Ocean). It is only a little over two hundred years since the first European colonists found themselves in eastern Australia (the Sydney of 1788), trying to grow wheat under conditions in the southern hemisphere that were completely different from those of their homeland, England. The first wheat crop, grown at the current site of Sydney's Botanic Gardens, yielded little more than the few bushels that were sown. In contrast to those early days, Australia is now a major exporter of wheat and of many other grains (Table 1).

New Zealand was colonized at a time and under circumstances similar to those of Australia. Grain production in New Zealand is now also significant, but generally not to the extent of being involved significantly in grain export. The many nations of the Pacific islands are not significant producers of grain species. Instead, they are importers of grain and flour products. For these reasons, this article concentrates on grain production in Australia.

Historical Perspective

In its early decades, the Australian grain-growing industry fluctuated from under-production through self-sufficiency to occasional periods of excess (Table 2). Wheat was the main grain grown, being needed for bread making. Farmers had to contest dry conditions, poor soil in some of the areas cultivated initially, attack by the rust pathogen, a reversal of seasons from their previous experience, and varieties that were poorly adapted to the new continent. This last problem was realized in the latter half of the nineteenth century by far-sighted farmers, by staff of "experimental farms," and by an amateur, William Farrer, whose profession as a surveyor took him into the heart of the wheat-growing regions. Whereas farmers attempted to develop improved varieties by selecting seed from plants that looked better than the rest of the crop, Farrer set about the (then) new technique of cross-breeding to increase the genetic diversity from which to select better genotypes.

An example of the selection method is given in Table 2; the extension of wheat growing into drier

Table 1 Production of the range of grain species in Australia (as 5 year averages of recent years)

Grain species	*Production in (kt)*	*Proportion exported*	*Domestic and export uses*
Cereals			
Wheat	22 400	75%	50% domestic use is food, mainly in bread; 40% domestic use is animal feed, also for starch-gluten manufacture
Barley	6500	70%, including 10% as malt (grain equivalent)	Most is used domestically as animal feed; 7% domestic use for malting and food
Oats	1400	15%	10% domestic use is for human food; 90% domestically for feed
Sorghum	1800	22%	All domestic use is as animal feed
Rice	1400 (as milled grain)	50%	Domestic and export for food as a range of rice types
Triticale	760	2%	All domestic use is as animal feed
Maize	360	10%	25% domestically used for food; otherwise feed
Oilseeds			
Canola	1700	77%	Oil is pressed from the grain, and the residue is used for animal feed
Cottonseed	1040	75%	As for canola
Sunflower	120		As for canola
Pulses			
Lupins	1500	56%	Used for feed domestically
Field peas	400	80%	Used overseas for food as splits and flour
Chick peas	200	95%	Food forms overseas include dhal, besan, hummus, and felafel
Faba beans	250		Food uses overseas include snacks and felafel
Lentils	120		Food uses
Mung beans	25		Exports to Asia and Africa used as splits and sprouts

Data from Australian Bureau of Agricultural and Resource Economics, Canberra, Australia. www.abareconomics.com.

regions was attributed to the selection of "Purple Straw" (an earlier-maturing wheat) from a field of "Red Straw" by a South Australian farmer in ~1860, just before the introduction of cross-breeding. The recent use of cross-breeding to produce new wheat varieties is shown in Figure 1. In nearly all cases, crosses have been made, but there are still a few new varieties that have arisen as selections from an already existing variety, such as the selection of "Meering" from the former wheat "Condor," which was presumably released as a mixture of a few genotypes.

Farrer's use of cross-breeding was partly aimed at developing wheats with grain quality suited for export to England by combining the dough quality of Canadian Fife wheats with the drought tolerance of wheats introduced from countries such as India, Palestine, and South Africa. This vision led him to enlist the help of the agricultural chemist, Frederick Guthrie, to evaluate the milling and baking quality of the small samples of his many cross-bred lines. Thus, started the development of small-scale test methods and (probably) the world's first breeder–chemist association, a combination that is now an integral part of the improvement of grain quality for all species. Subsequent years brought the excess production of wheat that justified Farrer's vision of export to England, largely as a result of the development of new wheat varieties (Table 2). These contributions by Farrer were recognized by the issue of $2 bank note when Australia changed to decimal currency in 1966 (Figure 2).

However, the greatest expansion in wheat production has occurred in the second half of the twentieth century, with production expanding from ~2 million tons (Mt) in 1940 to a high of almost 25 Mt in 1999/2000. Nevertheless, production has fluctuated on occasions due to drought. As a recent example, the high of 2000 contrasts with the drought year of 2002/3, when the national wheat crop was only a little over 10 Mt, less than half of the crops either side (~24 Mt in both 2001/2 and 2003/4). Similar reductions in production were experienced for all grains in the 2002/3 drought year.

Diversification of Markets for Australian Grains

Further improvements in the quality of wheat varieties and in management practices through the twentieth century extended opportunities for grain

Table 2 Historical developments in the Australian wheat industry

I. Period of foundations 1788–92	
1788	Eight acres are sown to wheat at Farm Cove, Sydney.
1790	James Ruse grows "bearded" wheat on a few acres at Rose Hill, Parramatta.
1792	About 200 acres cultivated to wheat in the colony.
II. A wheat market is established 1793–1824	
1793	The colony is self-sufficient in wheat and maize.
1803	Rust destroys wheat crops in Sydney's Dundas Valley.
1804	Abundant yields of "Common Brown" wheat in the Sydney district bring self-sufficiency again, but prices are low.
1810+	"White Lammas" and "Red Lammas" wheats from England and Scotland are cultivated, mainly in coastal regions. "White Lammas" was late-maturing and poor in baking quality.
1811	James Ruse makes himself a plow; previously most tillage was by hoe.
1822	Various wheats are introduced by the newly established Agricultural Society of New South Wales from England, South Africa, India, and Egypt.
III. Period of insufficient expansion 1825–55	
1850	"Red Straw" and "White Essex" (a Lammas type) are introduced.
IV. Period of declining yield 1855–96	
1860+	South Australia's climate and geography favor quality-wheat production, and grain is exported to England.
1860	"Purple Straw" (an early-maturing wheat) is selected, probably from a field of "Red Straw" by a South Australian farmer. This selection starts an extension of wheat growing into drier regions.
1880	Introduction of Ganz steel roller mills from Hungary alters quality requirements.
1881	"Du Toit's" wheat, early-maturing and rust-resisting, is introduced from South Africa by Dr. Schomburgh, Director of the Adelaide Botanic Gardens. From this introduction, James Ward, of Port Pirie, selects a rust-resisting high-yielding wheat named "Ward's Prolific."
1882	Correspondence with "The Australasian" newspaper prompts the English-born surveyor W. J. Farrer to make plans for wheat improvement by cross-breeding and selection, thereby going beyond the previous practice of selection only for wheat improvement.
1889	Farrer's first crosses are attempted at his property, Lambrigg, near Canberra. The variety "Blount's Lambrigg" is selected from cross-bred material provided by A. E. Blount of Colorado, USA.
1890	Disastrous wheat losses, due to rust, prompt the First Rust-In-Wheat Conference to be convened. Farrer's letter to the Conference calls for cross-breeding as a means of improving both rust resistance and grain quality.
1893	F. B. Guthrie, recently appointed chemist with the Department of Agriculture of the Colony of NSW, devises small-scale tests of milling and baking quality for selecting suitable parents and cross-breds from Farrer's breeding program. Improvement of quality is thereby made possible.
1893	Hugh Pye produces "Improved Steinwedel" at Dookie College, Victoria, by making the cross (Steinwedel × Purple Straw) × Steinwedel.
1893	A date suggested as the origin of cereal chemistry as a discipline, due to activities in Australia and overseas.
1895	Farrer's "Yandilla" is the first of a new generation of wheats, designed to combine Fife quality with the drought resistance and earliness of Indian wheats.
V. Period of rapid expansion 1896–1930	
1896	Local millers are forced to modify their machinery to suit imported North American Fife wheats due to local shortages. They are thus more ready to accept Farrer's stronger wheats, which they had previously rejected.
1898	Farrer is appointed officially as "Wheat Experimentalist" to the NSW Department of Agriculture on an annual salary of 350.
1900	Release of "Bobs," reportedly obtained by crossing a selection from "Blount's Lambrigg" with "Bald Skinless Barley" by Farrer in 1896. It became popular throughout Australia and represented a breakthrough in the production of "strong" wheat.
1901	Export of 25 million bushels of wheat and flour.
1901	Release of "Federation," selected by Farrer from his cross in 1895 between "Purple Straw" and "Yandilla." Though it fell short of his quality and disease-resistance goals, its yield made it the most popular wheat in Australia from 1910 to 1925. It was also widely grown in USA, India, and other countries.
1906	Death of Farrer, and suspension for many years of quality-directed breeding.
1911	NSW "Strong White Wheat" class is established to segregate Farrer's strong wheats. Export of 64 m bushels of wheat and flour of all classes. The contrast between this harvest and that of 10 years before is due largely to Farrer wheats such as "Federation."
1924	Release of "Ghurka," bred by G. S. Gordon in 1916, becoming a leading Victorian variety in its own right, and also a parent of many important soft wheats.
1929	The variety "Bencubbin" commences its phenomenal rise to popularity, not only in Western Australia, where it was bred by E. L. Limbourn, but throughout Australia.
VI. International marketing expansion 1930–48	
1936	The Gepp Royal Commission recommends that breeders should "endeavour to produce new varieties which have the quality of strength."

Table 2 Continued

1945	Availability of "Gabo" wheat saves many farmers from ruin due to rust. It starts Australia's reputation for high-protein baking-quality wheat.
1946	Introduction of "Insignia," selected for tiller survival, permits further extension of the wheat belt into drier areas.
VII. Grain quality targeted to specific market needs 1949–70	
1950+	Segregation of specific truck loads of high-protein wheat of selected varieties as Prime Wheat grades by the Prime Wheat Association, in northern New South Wales.
1956	Release of "Dural," the first Australian-bred durum wheat.
1957	Passage of the Wheat Research Act through Federal Parliament, and the consequent formation of the Wheat (Industry) Research Council, later to be replaced by the Grains R&D Corporation with responsibility for research on the wide range of agricultural grains.
1960	Naming of "Gamenya," derived from "Gabo" by I. A. Watson. Though bred in the east, its greatest impact was in Western Australia and as an ideal noodle wheat.
1960+	Growing market awareness, involving an active acknowledgment that about three-quarters of the Australian wheat crop is exported for "exotic" uses, leading to research initiatives on noodles, flat breads, and steamed bread.
1967	"Timgalen," issued by Sydney University, offers excellent quality with high-protein potential, disease resistance, and agronomic qualities that earned it a continuing unrivalled position for prime-wheat production.
1970+	Introduction of near-infrared spectroscopy revolutionizes the analysis of protein and moisture in grains.

exports. Initially these exports were to England, where the grain was used for traditional products, mainly bread. This situation has changed dramatically in the subsequent century. In recent decades, Australia has produced ~5 times more than its domestic needs, so that ~75% of the wheat harvest is exported. Currently, exported wheat goes to a wide range of countries, including Egypt, Indonesia, Iran, Iraq, Japan, and China.

In the early stages of the diversification of export markets (in the 1960s), it was realized that the wheat was being used for the production of a diversity of foods that could then be classed as "exotic," such as "Arabic" flat breads in the Middle East and a range of noodles and steamed breads in Asian countries. Furthermore, in countries such as Indonesia, even the manufacture of leavened bread involved nontraditional methods that required wheat of quality different from the English market.

Accordingly, experts were brought to cereal chemistry laboratories in Australia from the new export markets to demonstrate the production of these exotic products. Figure 3 shows an expert from the Middle East with experimental Arabic "pocket" breads, both from normal and small-scale baking. As a result of seeking this expertise, it was possible for wheat breeders to select new varieties that would suit these quality requirements. The resulting research led to the establishment of specifications for the wide range of wheat-based products made around the world. With the publication of these findings, advantages of the knowledge have flowed to the countries involved and to other exporters.

Another form of diversification came with the challenge presented to wheat growers by the sandy soils of Western Australia, due to the lack of soil nitrogen. An efficient solution to this problem was the introduction of grain-legume crops in agronomic rotation with wheat. The ability of the legumes to fix atmospheric nitrogen led to the provision of a natural source of nitrogen fertilizer, plus the welcome harvest of other grains, particularly lupins and various pea and bean crops (Table 1). These pulses have only emerged as important crops since the 1980s. Expansion of production has depended significantly on the growth of export markets. Recent expansions in wheat and pulse production have warranted the erection of new terminal storage facilities in Perth, Western Australia (Figure 4).

Another form of agricultural diversification accompanied the down-turn in wheat prices during the 1980s. In addition to growing grain legumes, a valuable crop was supplied in the form of canola (rapeseed). Production of canola has continued, leading to the expansion of the oilseed-crushing industry (Table 1). The canola crop has expanded dramatically, production having tripled in the period 1996–99.

Wheat

The Australian Wheat Board has been responsible for the marketing of the wheat crop since its formation in 1939. In July, 1999, its status changed from an Australian Government Statutory Marketing Authority to a private company called AWB Limited. The original name ("The Australian Wheat Board") was abbreviated to the initials to build on its reputation, while also reflecting its wider role beyond wheat. It is

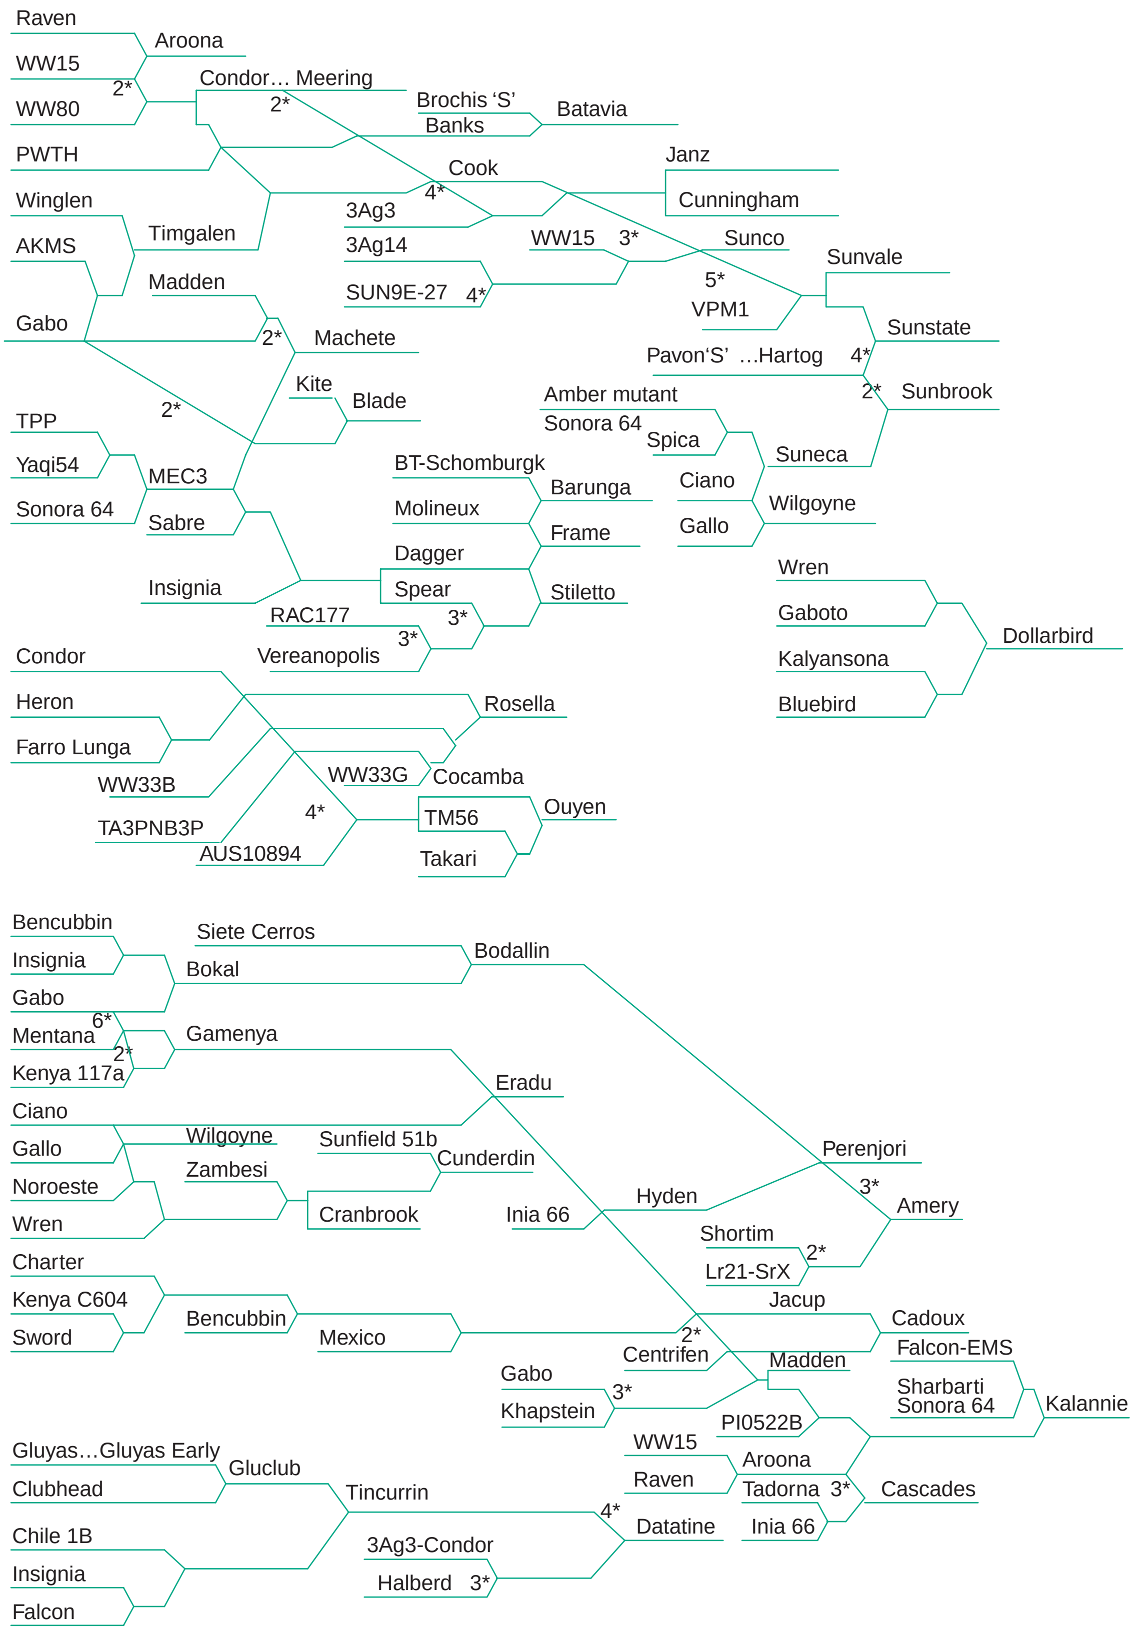

Figure 1 Pedigrees of recent prominent varieties of wheat grown in eastern and western Australia. Pedigrees are read from left to right. For example, Raven was crossed with the line WW15 to produce the variety Aroona. The line WW15 was crossed with WW80 and then crossed again (double backcross, 2*) to produce the variety Condor. The variety Meering was selected from Condor. Condor was a parent entering into the pedigrees of Banks and Cook. A sister line of Condor was a parent that also entered into the pedigrees of Banks and Cook.

Figure 2 The $2 bill, introduced with Australia's decimal currency in 1966, featured William Farrer – the wheat breeder responsible, in the period 1890–1910, for providing farmers with new varieties adapted to Australian conditions.

Figure 3 Arabic "pocket" breads baked experimentally by an expert from the Middle East in the laboratories of the Bread Research Institute of Australia (now BRI Australia) in the 1970s. This type of flat bread comes from the oven puffed into a sphere. On cooling it returns to its flat-bread form. Advice from such experts has assisted Australia in recent decades in providing wheat of the quality suited to specific market requirements.

still the single marketer of bulk Australian wheat internationally, although this is under review.

Wheat varieties registered in Australia are virtually all white grained, in contrast to the red-grained wheats that are common in other wheat-producing countries. This policy direction, taken in the very early days of the industry, has been recognized as a marketing advantage. For many years, only white-wheat varieties have been grown. In addition, the dry climate of Australia's wheat belt (mainly inland) ensures that the grain produced is very dry. Furthermore, marketers and bulk-handling corporations set rigid standards for the cleanliness of export wheat.

Consequently, Australian wheat has regularly been marketed as "clean, white, and dry." These three characteristics offer millers the triple promise of high flour extraction, namely, the lack of nonmillable material (clean), the white grain permitting a higher extraction rate before flour color is compromised, and dry grain offering less moisture to be paid for at the price of grain (if sold on "as is" weight).

Because of the high proportion of the Australian wheat crop that is exported (Table 1), marketing strategies must take into account the wide range of products for which it is used. Several of these are shown in Figure 5. The main products domestically are the many conventional forms of leavened bread. This type of baked product is in a minority for export uses, which are more likely to include products such as various Arabic flat breads, Chinese steamed breads, many types of noodles (made from hexaploid wheats), and pasta (made from tetraploid durum wheats). Durum wheats make up a small proportion of the crop, but this proportion is increasing.

To meet the wide range of quality specifications for these various products, there are many wheat grades with tight specifications. Varietal identity is an important part of the quality specifications, with a small group of varieties of similar quality type being permitted for each grade. Other specifications cover aspects of the plumpness of the grain, absence of contaminants and of insects, cleanliness, soundness, the absence of defects, and, importantly, protein content. This approach to grading and marketing is in great contrast to the Fair Average Quality (FAQ) era of the earlier part of the twentieth century, when FAQ was

Figure 4 The grain-storage facility in Perth, Western Australia. The very large storage capacity of this recent construction was warranted by the recent increase in grain production in Western Australia. The many storage cells are designed to accommodate the diversity of grain species and grades.

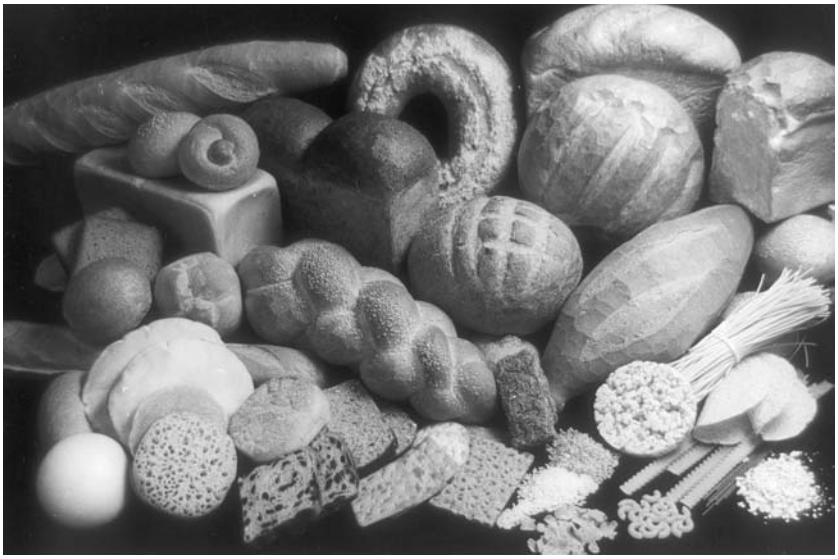

Figure 5 The range of food products made from Australian wheat. In addition to the many forms of leavened bread, Australian export wheat is used for products such as Chinese steamed bread (white sphere at lower left), Arabic flat breads (lower left), noodles (at right), crisp breads (lower center), and pasta (lower right).

determined as an estimate of quality expectations based on the type of grain that "happened" to be delivered.

The maintenance of grain quality in the current range of grades and classes requires strict systems for assessing grain quality when it is delivered. It is common for grain to be delivered directly from the field to the local silo (grain elevator or storage site), although on-farm storage is becoming more common. At the point of delivery, it is critical for the range of quality attributes to be determined quickly, to allow for the grain to be dumped into the storage cell appropriate to the grade to which it is allocated. In addition, grain samples are kept to represent the deliveries of each grower and to indicate the composition of the storage cells. These can further be analyzed subsequent to delivery.

Rice

Rice production and export is a significant industry for Australia. The annual average rice crop is milled to

produce the equivalent of almost 1.5 Mt of white rice (Table 1). It is grown within the irrigation areas of the Murrumbidgee and Murray river systems in southern NSW, with some further areas of production in Victoria, Western Australia, Queensland, and the Northern Territory. Farming operations are entirely mechanized. In the irrigation area, sowing occurs in September and October into dry seedbeds. Sometimes sowing involves the aerial dispersal of pregerminated seed into shallow water. After ~4 months, water is drained allowing the beds to dry prior to mechanical header harvesting. Yields are high by world standards, averaging over 9 t ha^{-1}, with some growers achieving 13 t ha^{-1}. Rice is generally delivered at relatively high moisture (20–22%) to avoid cracking of the kernels. Aerated storage is used to further reduce the moisture to ~15% prior to milling. All deliveries are sampled on delivery and are analyzed for moisture and protein contents by near-infrared transmission spectroscopy. Samples are also checked for variety and for defects.

Rice grown in New South Wales is vested in the Rice Marketing Board of NSW with the Ricegrowers' Co-operative Limited as its authorized buyer, who coordinate the production, storage, processing, and marketing of whole-grain rice and processed rice products. Much of the milled rice is provided for the domestic and export markets in branded retail packs, ready to go onto supermarket shelves. About half of the rice crop is exported, going to more than 40 countries, but Australian rice makes up only 3% of world trade. Papua New Guinea takes ~25% of Australian rice exports. Other significant export markets are the Pacific Islands, Hong Kong, and New Zealand.

Most of the rice grown in Australia is from medium- and long-grain Indica varieties. The long-grain varieties include the fragrant types. The hulls that are removed in the milling process are converted by incineration to high-carbon ash, which is used by the steel industry in Australia and overseas. The ash is used to coat the surface of open-hearth furnaces, thus trapping the heat and improving fuel efficiency. Fire-proof building materials have also been developed using this ash as a starting material.

Coarse Grains

Barley

Second in importance, based on volume and quality, is barley – of both domestic and export significance (Table 1). Export markets are mainly China, the Middle East, and Japan. Australia is the second most important country in world malting-barley trade, depending on seasonal fluctuations. The premium use of barley is for malting to produce beer. In addition to the export of malting barley, malt produced in Australia is exported for beer production overseas. Varieties are bred specifically for the purpose of malting, based especially on the production of brewery extract for fermentation purposes after malting. These are all two-row types; Australian six-row barleys are all of feed quality.

Animal feed is the destination of barley that does not meet the stringent requirements of the malting grades, due to failures in meeting specifications for variety, protein content, or absence of defects. Feed barley, together with sorghum and down-graded wheat, are the main grains for the animal-feed industry, their importance being greater because of the low production of maize in Australia.

Barley is also used for human food purposes both domestically and in export markets. Japan has emerged as a major user of food-grade barley. Some of the food uses involve pearling, to remove the bran and husk layers. In other cases, flour is produced and some of this is becoming used to produce high-fiber pasta products, taking advantage on barley's high fiber content in its cell walls (β-glucans and pentosans). The production of distilled beverages is another significant use of food-grade barley.

Oats

Most of the oat crop is used within Australia. It may serve on-farm as a forage crop to be grazed when plants are young, with the option of allowing the plants to mature and produce harvestable grain. Some varieties are suited to milling and processing for food purposes, but much of the crop is used as animal feed (Table 1).

Sorghum

Sorghum is a feed grain. Much of the crop is exported for this purpose. The main customers are Japan and Taiwan. Production is mainly confined to the warmer subtropical parts of Australia.

Cereal Rye

Flour produced from rye grain is used in Australia for European-style breads, biscuits, crispbreads, multigrain breakfast cereals, muesli bars, pet food, and special dietary foods that provide higher lysine, pentosan, and β-glucan content than other cereals. Production is minor in volume.

Triticale

The wheat-rye hybrid triticale has enjoyed reasonable popularity in Australia. Annual production is about

0.75 Mt (Table 1), making Australia the world's fourth largest producer of triticale, depending on seasonal fluctuations. Triticale's attraction has mainly been as an alternative to wheat for the stockfeed industry, which is the major domestic end user. However, efforts have been made to develop niche markets for human food.

Maize

Maize is a relatively minor crop in Australia, with annual production averaging ~0.33 Mt (Table 1), less than the production figures for all the major cereal grains. About 10% of the maize crop is exported. About one-quarter of the crop is used domestically as human food, mainly for breakfast cereals, sweet corn/vegetable uses, corn-based foods, and industrial manufacture of corn starch. The remainder is used domestically as stock feed. Industrial use of maize is minor compared to northern-hemisphere maize use, because Australian starch production is mainly based on wheat. Maize processing into starch relates mainly to special products such as high-amylose starch.

Pulses

Combined, the pulses (grain legume species) are the third largest crop in Australia (after wheat and barley) (Table 1). Much of the pulse production is exported. The pea and bean species are largely used overseas for human food purposes, especially for the Indian subcontinent. Australia is the largest producer of lupins; about half of the crop is exported. Australian lupins are largely based on the narrow leafed lupin *(Lupinus angustifolius)*. White lupin (*L. albus*) is also grown to a significant extent. The potential of the crop has been enhanced through breeding to reduce the levels of alkaloids, to decrease the risk of grain shattering, and to improve disease resistance.

Oilseeds

The canola crop has expanded dramatically since the 1990s, production having tripled in the period 1996–99. It was ~2.4 Mt in 1999, rather more than the recent five-year average given in Table 1. Cottonseed production given in Table 1 (a little over 1 Mt) is the volume of "white seed," after allowing for de-linting and de-hulling. About a quarter of this is crushed domestically for oil production. Production volumes are similar for sunflower and soybean (both 110 000–120 000 t annually). Peanut production is well below these at ~30 000 t. Lesser oilseeds include linseed and safflower. Australia is a significant exporter of oil crushed from these various oilseeds, especially cottonseed. The residues from oilseed crushing make important contributions to the stockfeed industry.

Consumption

Australians consume ~70 kg of wheat flour per person per year, mainly in the form of baked goods, but flour also goes into many processed foods. A significant part of this "consumption" (based on statistics) is due to the importance of the starch-gluten industry, which processes dough to separate the starch fraction, using some of the starch for paper manufacture. Wheat starch is also a significant food ingredient. The remaining gluten is dried and used as an additive for bread manufacture (both domestically and as a significant export commodity) and also for incorporation in a range of foods.

Another significant use of grains in Australia is the breakfast-cereal market, which is valued at Aust.$800 million. These and other grain-based foods represent an important part of Australia's exports of manufactured goods, primarily to the Pacific islands and to Asia.

Goodman Fielder is an important manufacturer of grain-based foods in Australia and New Zealand. Recently, Goodman Fielder had market shares in Australia of about half the packaged bread, cake mix, and snack-food markets, ~20% of breakfast cereals, ~66% of pastry, and ~30% of dessert mixes. In New Zealand, Goodman Fielder had about half of the packaged bread and potato-chip markets.

New Zealand

Significant volumes of barley and wheat are produced in New Zealand, as is shown in Table 3. Deregulation of the wheat industry some years ago accounted for significant changes in the structure of the industry, increasing competition and the likelihood of importation of grain. Grain yields for both wheat and barley are considerably higher on average than in

Table 3 Production of wheat and barley in New Zealand for the year 2003

Crop species	*Area sown (ha)*	*Production (kt)*	*Grain yield ($t\ ha^{-1}$)*
Wheat	55 000	324	5.9
Barley	82 000	449	5.5

Data from Statistics New Zealand. www.stats.govt.nz.

Figure 6 Wheat field and on-farm storage in the south of the South Island of New Zealand. As late as April (autumn), the standing grain is still waiting to be harvested.

Australia, being $\sim 6\,t\,ha^{-1}$. In further contrast to Australia, adequate on-farm storage for the crop is common (**Figure 6**), so that the grain buying and transport systems are different from those in Australia. Most of the New Zealand harvest is later than in Australia, where early deliveries may start in October. On the other hand, harvest time in the south of the New Zealand South Island may be as late as Easter time (late in the southern-hemisphere autumn).

Introduction

South America produces 106 800 000 ton (t) of cereals and 72 300 000 t of the main oilseed crops (Table 1). Forty percent of the world's soybean production and 10% of maize (Figure 1) are harvested

in South America. The combined share for all cereals is 5.18% (average of the triennium 2000–02).

Brazil and Argentina are important producers of grain and oilseed crops at a world level. Brazil is the main soybean exporter in the world and feeds its population with large harvests of crops such as rice and maize. Argentina is among the top five exporters of wheat, soybean, and maize.

The whole region possesses plenty of arable land and renewable water resources and, although economic uncertainty is endemic, prospects are positive for agricultural development. Improvement (better seed varieties, mechanization, and fertilizer use) in average yields of the major crops and increases in harvested area have boosted the region's production in the last decades.

Grain-based food preferences vary from country to country. Wheat (Argentina, Chile, and Uruguay), maize (Paraguay, Venezuela, Bolivia, and Colombia), and rice (Guyana, Suriname, and Ecuador) are the most important grain raw materials used for food preparation (Table 2).

Argentina

The Argentine Republic is the second grain producer and the main exporter in South America (Figures 2 and 3), with an average cultivated area for the last triennium of 27 160 000 ha and average harvest of 67 436 000 t. Since the 1990s, the harvested area increased by 36% and production by 66%. Technological advances, better seed quality, genetic improvement, and better crop management were the major factors in this development.

The Pampas, a rich humid plane in the central eastern part of the country, is the main area of grain production. Wheat was sown during 1999–2001 on an average of 6 000 000 ha with harvest figures of 14 570 000 t. The Buenos Aires province produces 62% of all wheat produced in the country. Argentina is the fifth major wheat exporter, averaging 9 570 000 t in the 2000–03 triennium. Brazil imports most of the Argentine wheat (from 62% to 82% of the total) and the rest primarily goes to Iran, Peru, Bolivia, Chile, and South Africa.

Argentina exports wheat as a commodity but has recently started a small-scale trial to segregate its products based on quality aspects.

Internal wheat consumption is stabilized, with average figures of 4 600 000 t per year. Three-quarters of it is designated to bread production. During 2001, bread consumption was 2 160 000 t (75 kg per capita). Argentines prefer continental bread (70 kg per capita). The country has 12 000 bakeries where artisan continental bread is made daily.

Data from FAOSTAT data files.

Industrial bread (sliced wrapped white bread) only constitutes a 5% of the total intake of bread. Nevertheless, in recent years sliced bread has shown a steady increase in sales (mainly in supermarkets). Production of cookies has increased tenfold since the 1990s, reaching 285 000 t in 2002. Argentina is the largest consumer of cookies in South America, with an average of 7.5 kg per capita per year.

Durum wheat harvest, used mainly for pasta production, averaged 186 000 t in the 1999–2001 period. Argentina's pasta consumption averaged 6.8 kg per capita in 1999. Argentina exports 400 000 t of flour.

Maize is the second largest cereal crop in the country, in terms of acreage. Almost 3.5 million hectares (Mha) were sown in the 1999–2001 period with an average harvest of 15 225 000 t per year. Two-thirds are usually exported (17% of the international market). Spain, Egypt, Chile, Peru, and Brazil are the major buyers of Argentine corn. Argentina is the sixth world producer of maize.

Sorghum figures, for the 1999–2001 triennium, amounted to 3 159 000 t per year and it is mainly destined for feedstuff. Japan is the major importer of Argentine sorghum.

The increasing trend, showed until 1998–99, of rice production has stopped. Average production for the 1999–2001 crops was 1 140 300 t.

Two other cereals with important acreage and production figures (over 500 000 t each) are oats and barley.

Oilseed crop production has been increasing steadily for many years now and altogether, they represent 52% of total grain acreage. The principal

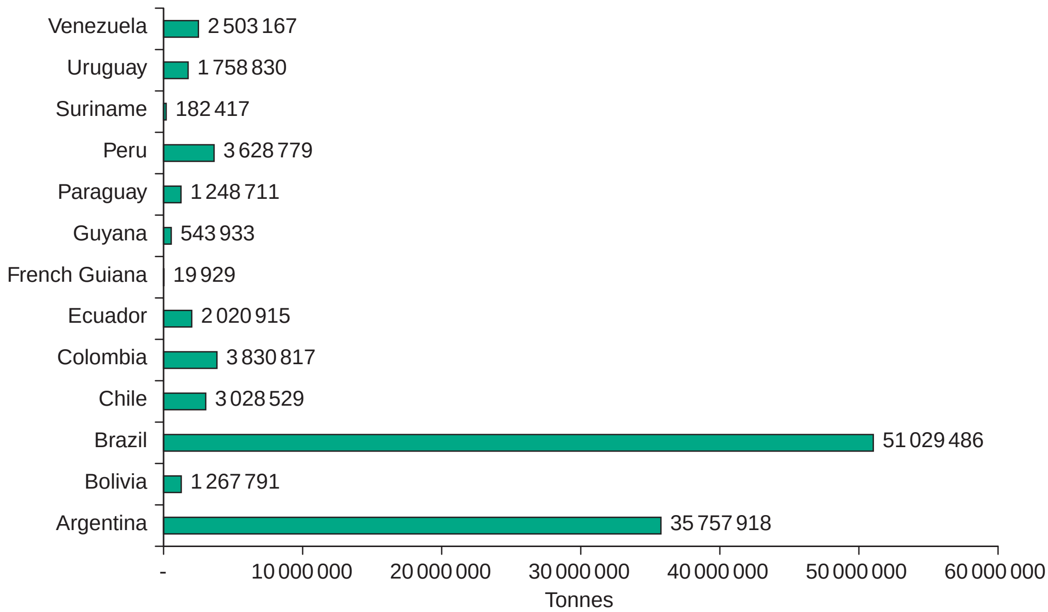

Figure 2 Average production of cereal crops in South American countries in the 2000–02 triennium. (*Source*: FAOSTAT agriculture data files.)

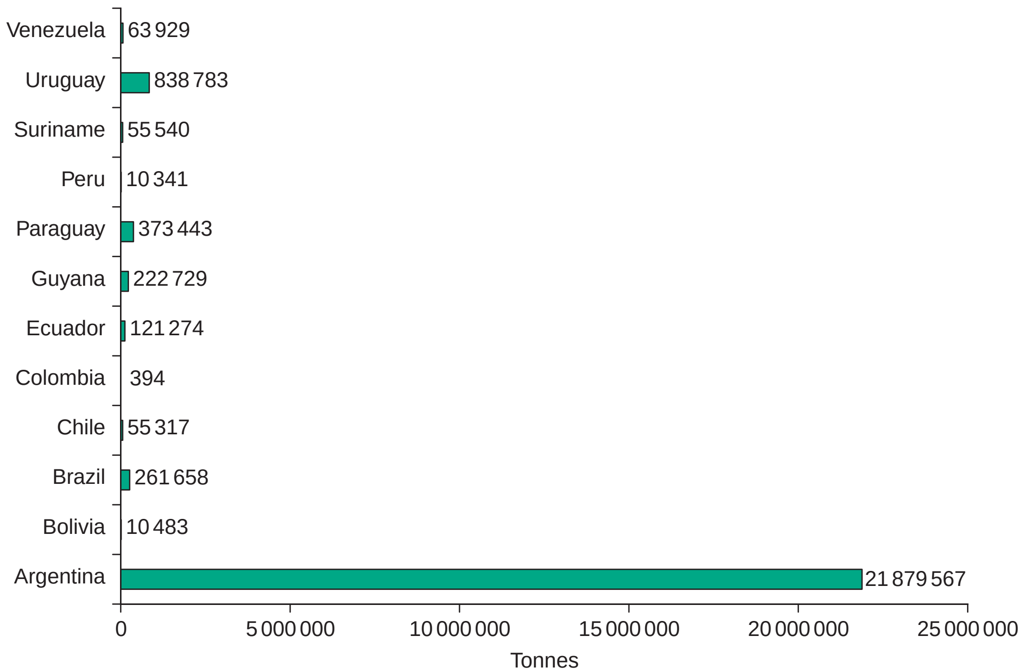

Figure 3 Average exports of cereal crops in South American countries in the 1999–2001 triennium. (*Source*: FAOSTAT agriculture data files.)

oilseed grown is soybean, which is also the leading crop in Argentina. Its acreage is 12 600 000 ha and production reached 30 000 000 t in the 2001–02 cycle. Argentina uses GM technology for its soybean cultivars along with nontillage technology. Profits from the crop production are very high. Nevertheless, there are growing concerns about the sustainability of resources involved in soybean production in the country. Soybean is mainly exported to China and Thailand.

Soybean oil is marginally consumed in the country (10% of all edible oils) and is mainly exported to India, Iran, Bangladesh, Egypt, and Morocco. European countries (Italy, Spain, Holland, and Denmark) import soybean pellets.

The second most important oilseed crop is sunflower, averaging for the 1999–2001 triennium 5 380 000 t. Yields have increased steadily during the last few years. Argentina is the major producer and exporter of sunflower oil, which is the main use for the sunflower seed. For the 1999–2001 period, Argentina produced 1 980 000 t and exported 1 475 000 t of sunflower oil. India, Iran, Egypt, and South Africa are the leading importers of Argentine sunflower oil. Exports of sunflower pellets averaged 1 134 000 t for the triennium 2000–02 and are mainly shipped to European Union countries. Other oilseed crops are groundnut, linseed, and canola.

Bolivia

Located in central South America, Bolivia is the poorest and least developed country in the region. Only 2% of the country's area is arable land and most of the population lives in rural areas. Agriculture employs 50% of the workforce and constitutes 23% of the gross domestic product.

In recent years this Andean country has consolidated a strong growth in oilseed crop production, particularly soybean. The triennium 2000–02 showed average production figures of 1 077 000 ton per year. The annual growth rate was 16.7% between 1990 and 2000. Santa Cruz state is the major producer, with an average yield of 1900–2000 k per ha without irrigation and fertilizers. The reason for the improvement in soybean production is the availability of new land at accessible prices, the existence of protected markets in the Andean countries, good finance options, national and foreign investments, and upgraded technology. In the 1990s, exports of oilseed crops increased by 747%. Soybean flour accounted for 64% of the exports, 26% of seed, and 10% of oil.

The second most important crop is maize (669 000 ton per year) followed by rice (291 000 ton per year) and wheat. Maize is the leading staple grain in the country. Bolivia also produces quinoa, a high-protein grain native to South America that was the staple food of the Incas.

Brazil

In 2000, primary agriculture accounted for 10.1% of Brazil's GDP and ~23% of the total labor force. Agricultural exports accounted for ~4% of the world's total agricultural exports and represented (in the year 2000) ~28% of the country's total exports, whereas imports accounted for only 8.5%.

Brazil is the major grain producer in South America, with an average cultivated area of 31 702 000 ha for the 1999/2001 triennium. The main production area is the South (Parana, Rio Grande do Sul, and Santa Catarina states), which produces almost 50% (48 893 000 t in 2001) of the total harvested grains (98 317 000 t in 2001) (these figures include beans (3 000 000 t in the year 2000)). The South East (12 682 000 t in 2001) and Central Western (28 451 000 t in 2001) regions are also important producers. The latter region has seen an unprecedented increase in the sown area of soybean of 5 000 000 ha since the mid-1990s.

Wheat production (2 708 000 t for the triennium 2000–02) does not satisfy internal demand. Two-thirds are imported almost exclusively from Argentina (6 789 000 t in 2001) favored by preferential trade terms between Mercosur partners (a common market/customs union formed by Argentina, Brazil, Paraguay, and Uruguay with Chile, Peru, and Bolivia as associates). Other exporters of wheat to Brazil are USA (100 000 t), Paraguay (88 000 t), and Canada (34 000 t). Brazil has been the largest or second largest wheat importer in the world since the 1990s and leads South American imports by an ample margin (Figure 4). Recently, the government has introduced incentives to increase wheat production in order to decrease imports. The principal wheat-producing states in Brazil are Parana (57%) and Rio Grande do Sul (34%).

Maize production for the 2000–02 cycles averaged 36 266 000 t per year, with almost 42 million ton (Mt) produced in 2001. Brazil is the third largest producer in the world, behind USA and China. The harvested area has been fluctuating between 12 and 14 Mha since the 1990s. Parana state is the major producer. The imports are quite variable (506 000 t in 1997, 1 728 000 t in 1998, 822 000 t in 1999, and 1 770 000 t in 2000) and mainly come from Argentina. Other exporters are Paraguay and USA.

Rice is a staple food in the country, so its consumption is correlated with the population growth. Most of Brazilian rice is cropped in uplands, particularly in the northern and mid-western regions. Rice production in the uplands occupied 2.4 Mha (64% of total area) in 1999, but contributed only 34% of the total grain production. The higher yielding system of rice cultivation, flooded fields, is more common in south and south eastern states. Production for the 1999–2001 seasons averaged 10 666 000 t per year of paddy rice. Rio Grande do Sul is the largest rice-producing state, producing almost half the total harvest. Brazil imported paddy rice 700 000 t–1 950 000 t

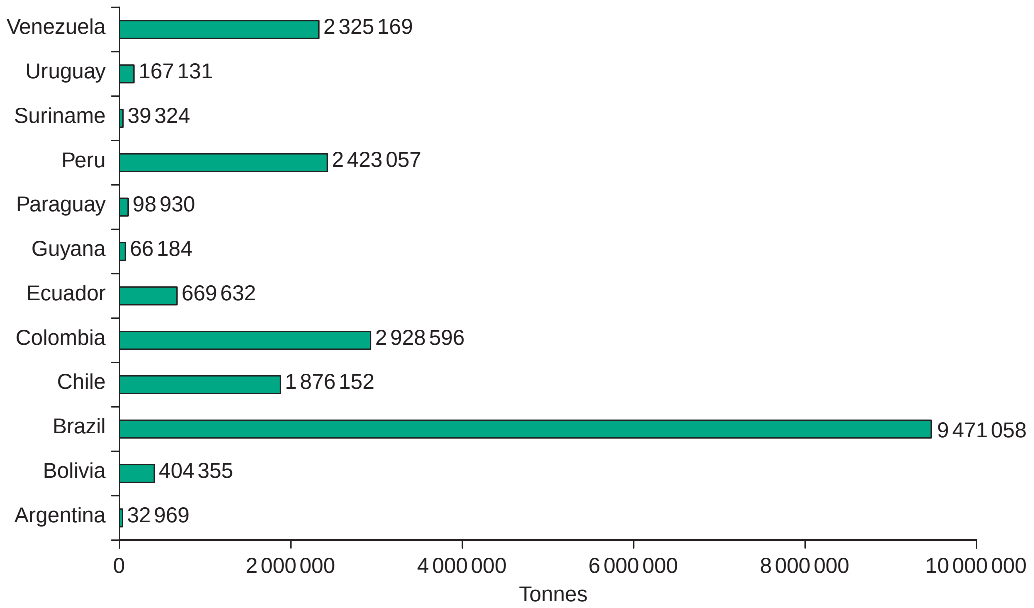

Figure 4 Average imports of cereal crops in South American countries in the 1999–2001 triennium. (*Source*: FAOSTAT agriculture data files.)

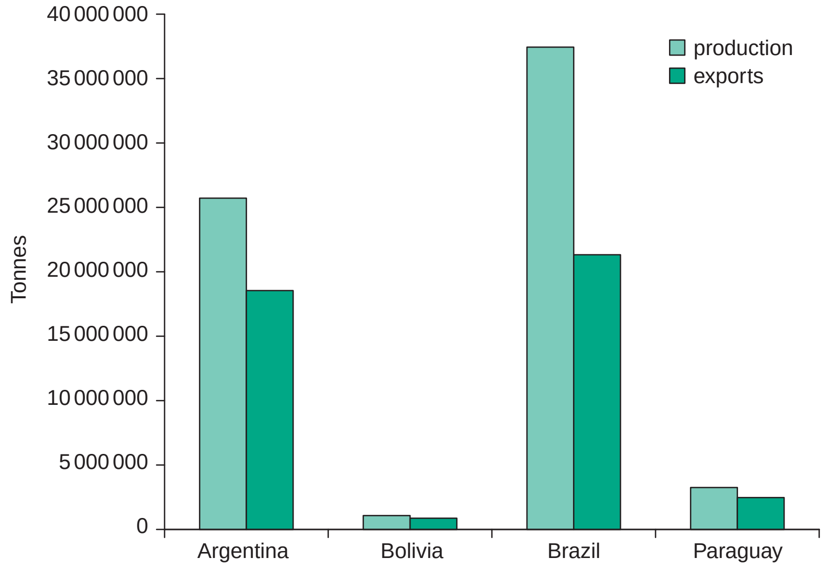

Figure 5 Major producers and exporters of soybean complex in South America (average 1999–2001 triennium). (*Source*: FAOSTAT agriculture data files.)

in the 1990s mainly from neighboring Uruguay and Argentina.

The soybean complex production (seed, meal, and oil) averaged 32 666 000 t in the 1999–2001 triennium and the harvested area averaged 13 417 000 ha. Mato Grosso, Parana, and Rio Grande do Sul are the main producing states. Brazil exports soybean and soybean meal to The Netherlands, France, Germany, and Spain. Oil is exported mainly to Iran and China (Figure 5).

Other important grains are sorghum, with a production of 896 000 t in 2001, barley (286 900 t in 2001), and oat (333 000 t in 2001).

Brazil's traditional, basic meal consists of rice and beans ("feijoada"). Following recent economic downturn, there was an increase in its consumption as people moved back to less expensive food. Yearly per capita consumption of rice and beans averaged 39.9 and 16.1 kg, respectively, for the 1998–2000 triennium. Beans are one of the main sources of

protein from vegetable origin in Brazil, second only to cereals. Brazilians consume half the total amount of beans destined for food in South America, with a daily intake of 9.7 g of protein per capita (average 1998–2000). Cereals (wheat, rice, and maize together) provide 20.4 g of protein per capita.

Chile

The Republic of Chile is a long, narrow country on the western coast of the continent, facing the Pacific Ocean. South-central Chile is where most of the grains are grown. The total grain production for the 2000–02 triennium averaged 3 000 000 t. Wheat (1 700 000 t per year), maize (780 000 t per year), and oats (330 000 t per year) are the most important crops. Maize (1 100 000 t per year according to 1998–2000 data) and wheat (540 000 t per year, 1998–2000) are also imported to fulfill internal demand. Chile is the main consumer of bread in South America and second in the world (97 kg per capita per year). Chileans are the third major consumers of pasta in the region (8.2 kg per capita in 1999). Chile is one of the three South American countries that fortify basic food (in this case, wheat flour) with micronutrients (iron).

Colombia

Situated in the northern part of South America, Colombia's agriculture contributes 14% of GDP, and 20% of the economically active population works in agriculture. In terms of volume, rice (2 318 000 t per year, 2000–02) is the second most important crop in the country, behind potato. Most of the rice-producing land is irrigated (84%). Maize production average figures for the 2000–02 cycles were 1 250 000 t per year. Maize is also a primary staple food for the Colombians, who prefer white maize. The third major cereal crop is sorghum, with average figures of 220 000 t per year in the 2000–02 triennium. Colombia is the second largest importer of grains in the region, behind Brazil. On an average, almost 3 000 000 t are imported per year (triennium 1999–2001).

Colombia is the third largest producer of beans in South America (120 000 t per year, average 1998–2000) and rates fourth in consumption with 3.5 kg per capita per annum (average 1998–2000).

Ecuador

Ecuador's economy is predominantly agriculture-based (17% of GDP), and its main grain product is rice. This crop is the source of employment for 22% of the active population. Its production for the triennium 1999–2001 averaged 1 340 000 t per year.

Maize production exceeds 500 000 t per year and may tend to increase in the future. Colombia buys almost 100% of Ecuador maize exports (72 963 t out of 73 002 t total maize exports in 2002). Maize is grown in small farms with much lower yields than the international average.

Wheat grown in the country (18 670 t per year) satisfies only 4% of the internal consumption (470 000 t per year in the 1999–2001 period). Major exporters to Ecuador are USA and Canada.

In Ecuador, the main edible oil source is palm (75%). Soybean production reached 77 772 t in 2002 and 97 500 t in 2003.

Ecuador has recently approved legislation for iron fortification of wheat flour.

French Guiana

Agriculture is concentrated in coastal areas (9000 ha of arable land), and paddy rice, with less than 20 000 t harvested in the last three seasons (2000–02), accounts for almost 100% of the produced grains.

Guyana

Annual crops are grown on the narrow coastal strip. Rice is almost the only grain produced, with an average of 540 000 t per year (paddy) in the 2000–02 triennium.

Paraguay

Another country with a strong agricultural and livestock sector (29% of GDP) is Paraguay. La Campina is the major producing area in the country (4 000 000 ha) with a mixture of traditional small farms and well-equipped medium/big farms.

Maize, cotton, and soybean are the most important crops. Paraguay is the third largest South American producer of soybean (3 175 300 ton per year in 1999–2001). Exports averaged 2 Mt in 1999–2001.

Flour production from oilseed for the triennium 1999–2001 averaged 842 000 t and oil production reached 236 000 t in 2001.

Paraguay has the second largest consumption figures for beans (5.5 kg per capita per year, average years 1998–2000) in the region.

Peru

The birthplace of the Inca's empire is located on the western coast of the continent, facing the Pacific. Peru has three distinctive environments: the coastal region,

the Andes, and the eastern jungle of the Amazon Basin.

One-third of its population is dedicated to agricultural activities. Nevertheless, Peru is a large importer of grains (third in South America). Almost 2 500 000 t are imported yearly (average 2000–02). Irrigated valleys in the coastal region are the most productive lands. Major crops are rice (1 900 000 t per year) and maize (1 300 000 t per year). Peru, together with Bolivia and Ecuador, accounts for all the world production of quinoa.

Peru is the second largest pasta consumer in the region with 250 000 t per year. On the other hand, bread consumption (38 kg per year) is not high.

Suriname

Most of the agricultural products are cultivated on reclaimed land in the coastal region. The main crop is rice, which accounts for almost all the harvested grain (paddy rice 182 300 t per year in 2000–02).

Uruguay

With only ~80% of its total area being agricultural land, Uruguay's economy predominantly relies on livestock and, to a lesser extent, on agriculture.

Uruguay produces 1 758 829 t per year of cereals (average, 2000–02). The main grain crop is rice (1 059 596 t per year of paddy rice for the same period). Other important crops are maize, barley, and wheat (averaging ~200 000 t per year each). Uruguay is the second largest exporter of grains in South America, although figures only reach 4% of the tonnage exported by Argentina. Most of the rice and barley is exported to Brazil. Iran is also an important buyer of Uruguay's rice and recently a small amount was exported to Japan for the first time.

Venezuela

Agriculture is concentrated in the "Llanos" regions and does not constitute a major component of the Venezuelan economy. The GDP for the agricultural and livestock sector is 5% of the country's total GDP. Maize, rice, and sorghum are the main crops. Venezuela imported 1 Mt of maize and 1.2 Mt of wheat (average 1999–2001). Maize (white maize) is the most important staple grain in the country. Venezuela is the largest consumer of pasta (13 kg per capita per year in 1999) in South America, second only to Italy (28.5 kg per capita) at the world level. Bean consumption averaged 4.1 kg per capita per year (1998–2000), the third largest in South America, after Brazil and Paraguay.

Venezuela is the South American country that fortifies many of its basic foods. Maize flour is fortified with vitamin A and iron and wheat flour is fortified with iron.

Future Prospects

Brazil and Argentina are likely to maintain their leadership in grain production in the region.

Increments in harvested area are expected, particularly in Brazil (in the virgin lands of "El Cerrado" where 90 000 000 ha could be transformed for agriculture use).

Yields are expected to continue to rise in Argentina, based on technological advances, but the country will have to ponder the benefits/risks of using genetically modified seeds, in terms of market acceptance and competitors' (Brazil does not grow GM crops) policies. Soybean will presumably continue to be the main cash crop. An estimate of 96 300 000 t of soybean will be harvested in South America in the 2003–04 crop year. This may probably be the first time that soybean harvest in South America will surpass US production.

Although Brazil is making great efforts to increase its harvested area of wheat, it is not expected that its role as major importer of this commodity will change in the near future.

Recent political changes in Brazil suggest a stronger collaboration between Mercosur countries that could provide a larger and better offer of agricultural products to the world markets.

L

LABELING OF GRAIN-BASED FOODS

J M Jones, College of St. Catherine, Arden Hills, MN, USA
C A Russell, Minneapolis, MN, USA

Overview

A well-devised label for all food products and for grain-based foods should help consumers select and purchase food for their needs. In addition to attracting consumers' attention, these labels are legal documents to assist with compliance and consumer protection. Thus, the label must clearly identify the product, comply with any legal standards for that product, e.g., standards of identity, and list the ingredients in descending order of their presence in the product. They must not label the product in any way that is misleading or misrepresents what is in the product. In many countries, products must list nutrient values in the product either on a per serving basis or on a per 100 g basis, the latter being the more common.

The emphasis on health and disease prevention has added another realm to labeling in some countries, the inclusion of health claims. Health claims must be approved by the appropriate regulatory body in a country and must be based on significant scientific agreement. In addition, there are claims known as nutrient content claims. These can state, for example, that "ACME cereal is a significant source of folic acid." Additionally, they can also contain structure function claims, such as "ACME cereal is a significant source of folate acid, which has been associated with maintaining heart health."

This article will talk about grain labeling in various countries of the world.

Food Labels

Labels for foods and grain-based foods throughout the world have similar functions. In addition to their obvious function of attracting the consumer's attention, food labels are legal documents in the country where the food is sold. All labels must contain the same basic information. Table 1 gives a detailed listing of information required in the USA. Each piece of information that is required has a very important function. Obviously, the name, style, and form tell the consumer what the product is. The net weight allows price and value comparisons of competing products which are sized differently. The address enables the consumer to contact the manufacturer for additional information, product complaints, and other matters. Probably the piece of information

Table 1 US food and grain label musts

Required item	*Extra information needed*	*Exemptions*
Common or usual name of the product	Style and form, if that is important	Standard of identity foods spices, colors (except FD&C #2), and flavors butter, cheese, and ice cream
Net weight	All packages must be labeled with both English and metric units. (If package contains between 1 and 4 pounds, its contents must be stated in terms of total weight in ounces and also weight in ounces and pounds.)	
Name, address, and zip code of manufacturer, distributor, or packer		
Ingredients in order by weight		
Statement that product contains artificial color or flavor (if any)		

that helps the consumer most is the ingredient statement. This gives the consumer some idea of the relative amounts of the various components in a product, since they must be listed in order by weight from the most to the least prevalent in the final product. Many consumers carefully scrutinize the ingredient statement for foods or additives that must be avoided, either by choice (as in the case of a vegetarian or one with religious food restrictions) or for medical reasons (as in the case of a person with an allergy).

The Nutrition Label

Some countries also require nutrition labels. However, the inclusion of nutrition information is voluntary, in other countries. In most countries, the format is also specified even if the labeling is voluntary. Nutrition labeling of all packaged foods including grain-based foods was required in the USA by the Nutrition Labeling and Education Act (NLEA), 1994. Required label formats for NLEA are given in Table 5.

Most grain-based foods are regulated by the US Food and Drug Administration (FDA). Those that include meat such as pepperoni pizza are regulated by the United States Department of Agriculture (USDA). Grain-based foods exempted from labeling are those served by restaurants and delis, those with very small packages (less than 12 square inches of available label space), and those produced by companies with very small annual sales.

The nutrition label is required to include information on total calories and calories from fat and on amounts of total fat, saturated fat, cholesterol, sodium, total carbohydrates, dietary fiber, sugars, protein, vitamin A, vitamin C, calcium, and iron. Other information is voluntary (Table 2). The nutrient content must be given for the food as packaged, but the manufacturer may choose to give nutrition information for the food as prepared or eaten, for example, cereal with 1/2 cup skimmed milk. Percentage of daily intakes are based on US dietary reference values (DRIs) (Table 3).

In North America, the nutrition label must be in legal serving sizes. For example, serving sizes of cakes cannot be made abnormally small so that these foods appear to be lower in fat and sodium than they really are. Serving sizes must be given in common household measures as well as by weight. If an item is packaged

Table 2 Examples of nutritional labels

Shortened format: label for vegetable soup

Nutrition facts		
Serving size		1 cup (245 g) (240 ml)
Servings per container		2
Amount per serving

Protein	0 g	0

*Percent daily values are based on a 2000 calorie diet.

[a] Federal Register (1993).

individually and is considered as a single serving, calories and fat must reflect the single item even though this might be larger than the legal serving size.

The law requires that the nutrient values printed on each package should be obtained from laboratory analysis or from approved databases. The inherent vitamin and mineral content may deviate as much as 20% from the labeled value in an individual sample. Added vitamins and minerals in fortified grain products must be at 100% of the stated amount at the end of the anticipated shelf life of the product. To be in compliance with the law, food manufacturers understate the vitamin and mineral value of the just-manufactured product to be sure of the product's compliance at the end of its shelf life. On the other hand, calories, fat, cholesterol, and sodium must never be labeled as less than the amount in the product.

The Australian-New Zealand Food Authority and most European countries also allow or require nutrition labeling. In these countries, the nutrition label values show the amount of nutrient per 100 g of food. This enables easy comparison by the consumer and works well, if consumers have an understanding of the number of grams in a slice of bread or bowl of cereal (Table 4). Since nutrient requirements are set by both national and other food authorities such as those for the EC, the percentage of requirements may also vary by country.

Table 3 Daily values on the nutrition label used for nutritional labeling purposes in the USA. The chart below lists the daily values used to calculate % daily value for the nutrition panel

Food component	*Daily value*[a]
Total fat	65 g[b]
Saturated fat	20 g[b]
Cholesterol	300 mg
Sodium	2400 mg
Potassium[c]	3500 mg
Total carbohydrate	300 g[b]
Dietary fiber	25 g[d]
Protein	50 g[b]
Vitamin A	5000 IU
Vitamin C	60 mg
Calcium	1 g
Iron	18 mg
Vitamin D[c]	400 IU
Vitamin E[c]	30 IU
Thiamin[c]	1.5 mg
Riboflavin[c]	1.7 mg
Niacin[c]	20 mg
Vitamin B_6[c]	2.0 mg
Folate[c]	0.4 mg
Vitamin B_{12}[c]	6.0 μg
Biotin[c]	0.3 mg
Pantothenic acid[c]	10 mg
Phosphorus[c]	1 g
Iodine[c]	150 μg
Magnesium[c]	400 mg
Zinc[c]	15 mg
Copper[c]	2.0 mg

[a] Daily value for adults and children aged 4 or older.
[b] Daily value based on a 2000 calorie reference diet.
[c] Optional on the nutrition label.
[d] Daily value based on 11.5 g per 1000 calories.

Label Descriptors

Grain-based foods can also be labeled using "nutritional descriptors" such as "light," "low-calorie," or "very low sodium." For example, rice cakes with under 40 calories might be labeled as a "low calorie" food. Table 5 gives a listing of other descriptors allowed in the USA. A reduced-calorie food must have calories reduced by at least one-third and must be labeled to compare it to the food it is replacing. Foods normally low in calories must be labeled so as not to confuse the consumer. For instance, celery may not be labeled as low-calorie celery, as some might think that labeled celery has fewer calories than unlabeled celery. For these foods, the label may read: "celery, naturally low in calories."

Nutrient Content, Health, and Structure-Function Claims

Nutrient content claims are allowed in the USA provided they are factual and use defined terminology. If a positive claim is made for one nutrient but the food contains another factor such as fat above the disclosure level listed in Table 6, then a statement about the level of fat must be made in the same place as the nutrient content claim.

Health claims may also appear on grain-based foods. Europe and Canada have begun to have some health claims. The UK has a health claim for

Table 4 Label of product mg/100 g

	Nutrition information	
	Per serving[a] *(1 biscuit – 10.4 g)*	*Per 100 g*
Energy	182 kJ (43 cal)	1749 kJ (416 cal)
Protein	0.54 g	5.2 g
Fat	0.95 g	8.1 g
Carbohydrate		
Total	8.11 g	77.9 g
Sugars	3.22 g	30.8 g

Sodium	39.0 mg	374 mg
Potassium	15.6 mg	150 mg

[a] Servings per package – 24.

Table 5 NLEA nutrition label terminology[a]

Free:	Contains no more than an amount that is "nutritionally trivial" and unlikely to have a physiological consequence
Fresh:	Can refer only to raw food that has not been processed, frozen, or preserved or to freshly baked bread
High:	A serving provides 20% or more of the recommended daily value
Less:	Term may be used to describe nutrients if the reduction is at least 25%
Light:	Term may be used on foods that have one third fewer calories than a comparable product. Any other use of "light" must specify whether it refers to the look, taste, or smell; for example, "light in color"
More:	Term may be used to show that a food contains at least 10% more of a desirable nutrient, such as fiber or potassium, than a comparable food
Source of:	A serving has 10–19% of the recommended daily intake of the nutrient
Fat free:	Has less than 0.5 g of fat per reference amount and no added fat or oil
Low fat:	Has 3 g or less of fat per reference amount and per 50 g of food if reference amount is small
Low in saturated fat:	Has 1 g or less of saturated fat per serving and not more than 15% of the food's calories come from saturated fat
(Percent) fat free:	Term may be used only in describing foods that qualify as low fat
Reduced fat:	Has at least 25% less fat per reference amount than appropriate comparison food
Sodium free and salt free:	Has less than 5 mg of sodium per reference amount
Very low sodium:	Has less than 35 mg per reference amount and per 50 g of food if reference amount is small
Low sodium:	Has less than 140 mg of sodium per reference amount and per 50 g of food if reference amount is small
Reduced sodium:	Has no more than half the sodium of appropriate comparison food
Sugar free:	Has less than 0.5 g of sugar per reference amount
Reduced sugar:	Has 25% less sugar per reference amount than appropriate comparison food
Calorie free:	Has less than 5 calories per reference amount
Low calorie:	Has less than 40 calories per reference amount and per 50 g of food if reference amount is small
Reduced calories:	Has 25% fewer calories per reference amount than the comparison food
Cholesterol free:	Has less than 2 mg of cholesterol per reference amount
Low in cholesterol:	Has 20 mg or less cholesterol per serving and per 100 g of food
Reduced cholesterol:	Has 25% less cholesterol per reference amount than appropriate comparison food

[a] From Federal Register (1993).

Table 6 Levels of ingredients disqualifying health claims on US labels

Fat	11.5 g
Saturated fat	4 g
Cholesterol	60 mg
Sodium	480 mg

whole grains foods. Health claims that might be found on grain-based foods in the USA are given in Table 7.

In the USA, if a food has one or more disqualifying ingredients (Table 6), the health claim may be used only if a disclosure statement is included.

Structure-function claims are popular in some countries such as Japan, which allows a number of claims for functional ingredients. These claims are also allowed in the USA under the Dietary Supplement and Health Education Act (DSHEA). Examples of structure-function claims include statements such as "Antioxidants maintain cell integrity" or "Fiber maintains bowel regularity." Neither NLEA nor DSHEA permit claims that "diagnose, mitigate, treat, cure, or prevent a disease or specific class of diseases." The only exception is that of classical nutrient deficiency diseases.

Organic Labeling

In the USA, the organic label for food and grains became official on 21 October 2002. Some consumers wish to select products that are produced by organic farming because of impacts on water quality and soil erosion and preservation of natural and agro-biodiversity. While many consumers use the organic label as a way to avoid genetically modified grains and other aspects that make them feel the food is safer or more nutritious than conventionally produced food and grain, there is little scientific data to support the idea that there is a difference. Nonetheless consumers all over the world want this choice.

Food carrying the organic seal or labeled as organic in the USA must adhere to the following rules. Organic food must be produced without:

- toxic, synthetic pesticides, herbicides, and fertilizers
- genetically modified organisms (GMOs)
- sewage sludge
- irradiation.

Organic grains must come from farms and ranches certified by a USDA accredited state or private agency. Organic grain products must have the name and address of the certifying agent displayed on the

Table 7 FDA approved health claims typically found on grain-based foods

Fiber-containing grain products, fruits, and vegetables and cancer
Sample claim. "Low-fat diets rich in fiber-containing grain products, fruits, and vegetables may reduce the risk of some types of cancer, a disease associated with many factors."
Requirements. Foods must meet criteria for "low fat" and, without fortification, be a "good source" of dietary fiber.
Typical Foods. Whole-grain breads and cereals, fruits, and vegetables.

Fruits, vegetables, and grain products that contain fiber, particularly soluble fiber, and risk of coronary heart disease
Sample claim. "Diets low in saturated fat and cholesterol and rich in fruits, vegetables, and grain products that contain some types of dietary fiber, particularly soluble fiber, may reduce the risk of heart disease, a disease associated with many factors."
Requirements. Foods must meet criteria for "low saturated fat," "low fat," and "low cholesterol." They must contain, without fortification, at least 0.6 g of soluble fiber per reference amount, and the soluble fiber content must be listed.
Typical Foods. Fruits, vegetables, and whole-grain breads and cereals.

Folate and neural tube birth defects
Sample claim. "Healthful diets with adequate folate may reduce a woman's risk of having a child with a brain or spinal cord birth defect."
Requirements. Foods must meet or exceed criteria for "good source" of folate, that is, at least 40 μg of folic acid per serving (at least 10% of the daily value). Folic acid content must be listed on the nutrition facts panel.
Typical foods. Enriched cereal grain products, some legumes (dried beans), peas, fresh leafy green vegetables, oranges, grapefruit, many berries, some dietary supplements, and fortified breakfast cereals.

Dietary soluble fiber, such as that found in whole oats and psyllium seed husk, and coronary heart disease
Sample claim. "Diets low in saturated fat and cholesterol that includes 3 g of soluble fiber from whole oats per day may reduce the risk of heart disease. One serving of this whole-oats product provides ? g of this soluble fiber."
Requirements. Foods must meet criteria for "low saturated fat," "low cholesterol," and "low fat." Foods that contain whole oats must contain at least 0.75 g of soluble fiber per serving. Foods that contain psyllium seed husk must contain at least 1.7 g of soluble fiber per serving.
Typical foods. Oatmeal cookies, muffins, breads and other foods made with rolled oats, oat bran, or whole oat flour; hot and cold breakfast cereals containing whole oats or psyllium seed husk; and dietary supplements containing psyllium seed husk.

Whole grain and heart disease
Diets rich in whole grain foods and other plant foods and low in total fat, saturated fat, and cholesterol may reduce the risk of heart disease and some cancers."
Dietary fiber content at least 1.7 g per 35 g serving.
Typical foods. Breads and cereals.

Soy protein and heart disease
Sample claim. Diets low in saturated fat and cholesterol that include 25 g of soy protein a day may reduce the risk of heart disease. One serving of (name of food) provides ? grams of soy protein.
Requirements. Scientific studies show that 25 g of soy protein daily in the diet is needed to show a significant cholesterol lowering effect. In order to qualify for this health claim, a food must contain at least 6.25 g of soy protein per serving, the amount that is one-fourth of the effective level of 25 g per day.
Typical foods. Soy beverages, tofu, temper, soy-based meat alternatives, and possibly some baked goods.

Vitamin B_{12}, B_6, and folic acid and reduced risk of heart disease
Sample claim. Foods containing vitamin B_{12}, as well as B_6 and folic acid, may reduce the risk of coronary heart disease.
Typical foods. Fortified cereal products.

product label. The USDA seal also assures imported organic food products have met the United States requirements.

There are four possible ways to use the organic label. These are given in Table 8.

Table 8 The USDA organic label definitions

100% Organic	Must contain only organically produced ingredients Can have organic seal
Organic	At least 95% of the products ingredients must be organic Can have organic seal
Made with organic ingredients	Must contain at least 70% organic ingredients Cannot have organic seal
Some organic ingredients	Products <70% organic ingredients Cannot use organic on main package panel Individual ingredients listed as "organic" on ingredient panel Cannot have organic seal

Labeling of GM Grain

Grain produced by biotechnology, if allowed to be sold, must be labeled in many countries. There are some exceptions. For example, grains that are sold in bulk would not need to be labeled in Australia. In the USA, labeling of GM grains is not required

Table 9 Grain labeling terminology for some common grains

Grain	*Whole or virtually whole grain*	*Refined grain*
Wheat	Whole wheat flour, whole wheat pastry flour	Wheat flour, white flour, refined flour, cake flour, pastry flour, all purpose flour, bread flour, gluten flour
	Wheat berries, whole grain farro, bulgur, cracked wheat, rolled wheat	Farina
	Whole wheat durum and whole wheat semolina, whole wheat cous cous	Durum and semolina, cous cous
Spelt	Whole grain spelt and whole grain spelt flour	Spelt and spelt flour
Rye	Whole rye or pumpernickel rye Rye berries, rolled rye	Light or white rye often listed as rye
Oats	Steel-cut oats, rolled oats, quick oats, old-fashioned oats, whole oat flour	
Corn	Ground whole cornmeal, whole grain masa harina	De-germed white or yellow cornmeal, hominy, grits
Rice	Brown rice[a], wehini and other colored rices (wild rice), brown rice flour	White rice, enriched rice
Barley	Whole or naked barley, minimally pearled barley, and their flours	Fully pearled barley and its flour
Quinoa	Whole or crushed	

[a] Grain length and variety do not matter – in other words there can be long grain, brown “basamati,” and there can be the refined version as white basamati.

as the US FDA views that there is no safety issue associated with these products.

Labeling Issues Specific to Milled or Processed Grain

Specific terminology is used to describe various grain components from various stages of milling and processing. Consumers are frequently unable to determine if a product is made from whole or refined grain and will incorrectly label a product as whole grain when it is not (Table 9). They often use color as a guide or infer incorrectly from a myriad of label and ingredient terms. For some, whole grain must refer to grain that is in its uncrushed, innate state and reject all but whole kernels (berries) as having the label of whole grain foods. However, this view is not widely held and most think that whole grain can be the crushed parts of that grain so long as all the parts are found in proportions that are present in the intact kernel.

Color is often used by consumers to determine if a product is whole grain. Thus, rye breads are often thought by US consumers to be whole grain because of their dark color. However, many US rye breads are made primarily with rye endosperm and colored with caramel color or molasses. Even those products sold as “pumpernickel bread” in the USA may contain little whole grain rye even though the bread’s namesake was originally made with whole grain rye and pumpernickel flour is whole grain rye. Color for wheat breads can be equally deceptive where there is little or not whole grain but the product is deemed by consumers as dark bread and therefore whole-grain containing. Some whole grain cereals, especially oats and corn, are light in color so consumers mistakenly think the products from these are from refined grains.

Label descriptors are also confusing. Some consumers assume that descriptor words such as organic, natural, or 100% Red River Valley wheat makes the product whole grain. Many do not know that when wheat flour is the first ingredient, it means that the flour is from milled wheat and is a refined product. Some people do not understand that enriched flour means that nutrients have been added to white flour. Depending on the proportions of other ingredients it may or may not provide a significant amount of whole grain to the diet. Products labeled “multigrain,” “seven grain,” or “nine grain” may contain relatively little whole grain. Even products listed as containing either bran or germ are not technically whole grain and in many products these ingredients are not found in high amounts. Only when products are labeled as made from 100% whole grains or have whole grain as the first listed ingredient can the consumer be certain that 51% of more of the grains in the product are whole grains.

Currently, there is a whole grain health claim in the USA and the UK to help consumers identify products that are whole grain. This needs to be modified as the health claim works well for low-water products such as cereals but works poorly for products such as bread which are high in water or cookies, which, even if

prepared with all whole grain flour, would not have 51% of the total ingredients as whole grain. Perhaps a seal which tells the consumer the portion of whole grain per serving would help make the label more consumer and whole grain friendly.

Summary

Labeling of grain-based foods helps consumers make an informed purchase to meet their individualized nutritional needs. Legally, labeling helps with compliance and consumer protection. Nutritionally labeled products are found in many major markets. With products and the global markets expanding, perhaps a standardized format would be useful to both the processor and the consumer. Organic labeling protocols are found in many parts of the globe and are popular for many consumers as a way to avoid GMOs and for a sense of increased control of their food choices and perhaps some environmental benefits. So far there has been little scientific evidence of the nutritional or food safety benefits of organic grain-based foods over conventional ones.

Terms surrounding grains and their milling treatment such as pumpernickel, pearled, and de-germed continue to confuse consumers and the ability of consumers to make informed choices as to what is whole grain difficult. Agreement as to what is whole grain and how to label it must be sought. A seal or an expanded health claim to help consumers may be important if the goal to increase whole grain consumption is to be met.

LENTIL

Contents

Breeding

W Erskine and A Sarker, International Center for Agricultural Research in the Dry Areas (ICARDA), Aleppo, Syria

Introduction

Lentil (*Lens culinaris* Medikus subsp. *culinaris*) is an important pulse crop that has been traditionally grown in West Asia, South Asia, Ethiopia, North Africa, and, to a lesser extent, in southern Europe. It is also cultivated in South and North America, and in Oceania. Its seed is a rich source of protein and other micronutrients (Fe, Zn, β-Carotene) for human consumption, and the straw is a valued animal feed. Since its domestication, lentil has been grown in rotation with cereals, which provides a sustainable cropping system.

Although lentil was cultivated as early as 8000 BC in West Asia, it remained an under-exploited and under-researched crop until recently. Systematic research for its improvement started in some national institutions and at the International Center for Agricultural Research in the Dry Areas (ICARDA), Syria, in the 1980s. Under the Consultative Group of International Agricultural Research (CGIAR), ICARDA has a world mandate for lentil improvement. The lentil improvement program at ICARDA is closely linked with the national agricultural research systems and with advanced research institutes in the world to address this mission.

The breeding objectives at ICARDA and in national programs are targeted to address the specific needs of different agro-ecological regions. A world collection of wild and cultivated lentil germplasm is maintained at ICARDA and has been instrumental in the development of improved genetic stocks suitable for different environmental niches. Except for a few traits, sufficient variability for important economic characters including stress resistance is present in these germplasms for use in breeding program. Following a bulk-pedigree method, the lentil-breeding program at ICARDA constructs new genotypes to deliver to the national programs. To date, a total of 81 lentil varieties with combination of various desirable traits have been released by 29 national programs emanated from ICARDA-supplied germplasm.

Origin and Domestication

Cultivated lentils originated in the Near East arc. *Lens culinaris* Medikus ssp. *orientalis* (Boiss.) Ponert, which closely resembles the cultivated species *L. culinaris* ssp. *culinaris*, is widely accepted as the progenitor species. From archeological evidence of carbonized remains it is concluded that the progenitor of cultivated lentil, *L. culinaris* ssp. *Orientalis*, originated in the Near East arc. Such carbonized remains appear in early Neolithic settlements which date back to 7000–6000 BC. Ladizinsky reviewed evidence for the center of origin and domestication of lentil.

The domestication of lentil occurred, together with that of emmer and einkorn wheat, barley, pea, chickpea, bitter vetch, and flax, during the Neolithic Agricultural Revolution, which is expected to have taken place in the eastern Mediterranean around the eighth and seventh millennia BC. Lentil culture spread rapidly with that of Neolithic agriculture to the Nile Valley, Europe, and Central Asia. It was part of the Harappan crop assemblage in Indian subcontinent between 2250 and 1750 BC. After AD 1500, the Spanish introduced lentil to South America via Chile. More recently, it has been cultivated in Mexico, Canada, the USA, New Zealand, and Australia. In North America, research on adaptation of lentil started in the late 1970s and it became an important crop of Canada and the USA. According to recent reports, Canada ranks third in area and production, of which ~95% is grown in the province of Saskatchewan. Lentil became an important crop component in the Palouse region of northwestern USA. Lentils were introduced in Australia very recently with only 500 ha under cultivation in 1993. Currently, however, it is grown in 125 000 ha of land with the state of Victoria being the major producer.

Phylogeny

Tournefort was the first to use the word *Lens*, a Latin word to designate a specific genus that describes the seed shape of the cultivated lentil. The genus *Lens* Miller belongs to the order Rosales, suborder Rosinae, family Leguminosae, and subfamily Papilionaceae and is in the tribe Vicieae. All species in the genus are diploid with $2n = 14$ chromosomes and have similar karyotypes.

The taxonomy of *Lens* has undergone numerous changes in recent years. Analyzing previous findings based on origin and spread, morphological, cytological, cytogenetic observation and more recently on the basis of isozyme and molecular studies, *Lens* taxonomy has been reassessed. The genus now consists of seven taxa split into four species.

1. *Lens culinaris* Medikus;
   (a) subsp. *culinaris*
   (b) subsp. *orientalis* (Boiss.) Ponert
   (c) subsp. *tomentosus* (Ladiz.) M. E. Ferguson *et al.*
   (d) subsp. *odemensis* (Ladiz.) M. E. Ferguson *et al.*
2. *Lens ervoides* (Brign.) Grande;
3. *Lens nigricans* (M. Bieb.) Godr.; and
4. *Lens lamottei* Czefr.

Use of Lentil and Its Nutritional Quality

Lentil is predominantly eaten in South Asia as boiled or fried "dhal." It has a soup-like consistency and is usually eaten with unleavened bread ("roti"). Boiled rice is also served as a staple with lentil dhal. "Khichuri" is made from a mixture of split/de-hulled lentil and cracked wheat or rice. In West Asia and North Africa, "Mujaddarah," made of whole lentil and immature wheat seed, is a popular dish. Of course, lentil soup is popular all over. Also, lentil may be deep-fried and eaten as a snack, or combined with cereal flour in the preparation of foods such as bread and cake.

Numerous lentil-based foods require steaming or boiling the whole seeds, whereas others, including many versions of the popular lentil soup, call for the removal of the fibrous seed testa (de-hulling). Lentil processing includes cleaning, sizing, de-hulling, splitting, and polishing. Only red cotyledon, small-seeded lentil is de-hulled and large-seeded yellow cotyledon lentil is used as whole.

In West Asia, lentil is cultivated for its straw, in addition to its grain. In Syria, for example, a farmer's revenue from straw in a dry year is sometimes greater than from the seed. The straw comes from the traditional threshing process and includes broken branches, pod walls, and leaflets. The protein content of lentil straw varies from 5% to 7% and its digestible dry matter from 43% to 46%. There is limited genetic variation in straw quality.

The pattern of nutrients in the proximal composition of lentil is similar to that of other grain legumes, but seed protein content (19.5–35.5%), although similar to that of peas (*Pisum sativum* L.) and *Phaseolus vulgaris* L., is less than in soybean (*Glycine max* L. Merr.). Seeds contain low levels of fat. Fiber concentration is low and is largely within the seed testa, so the fiber in lentil meal can be reduced if it is de-hulled before grinding. In addition to high-quality protein, essential amino acids, and major minerals, its seed contains iron up to 505 mg per kg and zinc up to 330 mg per kg on a whole seed basis. Besides, among various vitamins, lentil seed contains 200 mg per kg of β-carotene.

The amino acid composition of the seed, as in other grain legumes, is complementary to that of cereals. The relatively large concentrations of lysine compensate for the minimal concentrations in the cereal grains, while the cereal grains compensate for the minimum concentrations of sulfur-containing amino acids in lentil.

Constraints of Production Addressable by Breeding

Average lentil yields are low because of limited yield potential of landraces, which are also vulnerable to a range of stresses. The major abiotic limiting factors to lentil production are low-moisture availability and high-temperature stress in spring, and, at high elevations, cold temperatures in winter. Among biotic stresses, the diseases rust, vascular wilt, and *Ascochyta* blight, caused by *Uromyces viciae-fabae* (Pers.) Schroet., *Fusarium oxysporum* F. sp. *lentis*, and *Ascochyta fabae* Speg. F. sp. *lentis*, respectively, are globally important key fungal pathogens of lentil. Other diseases such as botrytis blight (*Botrytis cinerea* Pers.), stemphylium blight (*Stemphylium botryosum* Wallr.), collar rot (*Sclerotium rolfsii* Sacc.), root rot (*Rhizoctonia solani* Kuhn), and stem rot (*Sclerotinia sclerotiorum* (Lib.) de Bary) are localized problems. Besides, constraints to productivity include agronomic problems of pod dehiscence and lodging.

Adequate variability for all these traits is known to exist within the genetic resources of the crop (wild and cultivated), allowing manipulation through plant breeding. By contrast, several other important traits (such as biomass yield, pod shedding, nitrogen fixation, resistance to pea leaf weevil (*Sitona* sp.) and aphids, and the parasitic weed broomrape (*Orobanche* sp.)) are not currently addressable by breeding because of insufficient genetic variation.

Available Genetic Resources and Variation among Them

The lentil-breeding program at ICARDA is built upon the foundation of the germplasm collections and their efficient use. A large number of germplasm accessions are conserved at ICARDA under FAO auspices, elsewhere at the National Bureau of Plant Genetic Resources, New Delhi, India, Vavilov Institute of Plant Industry, St. Petersburg, Russia, and at United States Department of Agriculture (USDA), USA. The ICARDA collection is by far the largest which comprises 9646 cultivated and 479 wild relatives (Table 1). Among cultivated species conserved at ICARDA, ~11% have been developed at ICARDA through cross-breeding, and dispatched to national programs through the International Nursery Network. The Genetic Resources Unit of ICARDA has characterized 7500 for various morphological and phenological traits to date.

Marked variation among the characters for use in breeding and selection programs have been reported for various morphological characters, response in flowering to temperature and photoperiod, winterhardiness, iron-deficiency chlorosis, and boron imbalances, drought tolerance and resistance to fungal diseases (Figure 1), and viruses. Wild relatives also have shown considerable variability for morphological traits, winterhardiness, and resistance to drought *Fusarium* wilt, and *Ascochyta* blight resistance.

Table 1 Genetic resources conserved at ICARDA

L. nigricans	46	7
L. lamottei	9	3

Recent Trends in Lentil Production

World lentil production tripled since 1970s, from 1.05 million tons (Mt) in 1971 to 3.07 Mt in 2001, through a 119% increase in sown area and a 33.4% increase in average national yield from 611 to 815 kg ha^{-1} (Table 2). Three top-ranking countries, viz., India, Canada, and Turkey, increased their productivity and production. Although area under lentil cultivation in Turkey has gone down in the recent

Table 2 Trend in world lentil production (1971–2001)

Year	*Area (Mha)*	*Production (mt)*	*Yield (kg ha^{-1})*
1971	1.72	1.05	611
1981	2.27	1.45	640
1991	3.26	2.66	814
2001	3.77	3.07	815

Figure 1 Variation in maturity in lentil (drought escape through earliness).

years, it has increased greatly in India, Canada, Australia, and Ethiopia. Production in Asia is concentrated in a band stretching from Turkey in the west, to Bangladesh in the east, accounting for ~74% of world production. Among other Asian producers, China has recently started releasing lentil-related data and Bangladesh increased its productivity through release and cultivation of improved varieties. Iran, Nepal, and Syria have substantially increased production during the 1990s, whereas lentil-cultivated area and production in Pakistan has declined.

Twenty-three percent of lentil production is in North America, where, in addition to Canada, the USA maintains an area of ~80 000 ha and Mexico is a minor producer. In Africa, Ethiopia and Morocco are significant producers and Algeria, Sudan, Egypt, and Tunisia are minor producers. In South America, Argentina and Peru are major producers among six lentil-producing countries in the region. European lentil production is gradually decreasing, with France and Spain being the significant producers. In Oceania, Australia has come up as a significant producer with a production of 180 000 t in 2001.

International trade in small-seeded, red cotyledon lentil is dominated by Australia, Canada, and Turkey, whereas trade in the large-seeded, green lentil is primarily led by Canada and USA. Countries in the Indian subcontinent, and the Middle East are the major importers of red lentil, and southern Europe and South America import large-seeded green lentils.

Major Agro-Ecology and Breeding Objectives

Knowledge of the patterns of variation in the world germplasm collection is the key to understand factors affecting lentil adaptation to direct lentil breeding. The geographic distribution of variation of landraces in the world lentil collection for morphological characters, responses in flowering to temperature and photoperiod, winterhardiness, iron-deficiency chlorosis, and boron imbalances collectively illustrate the specificity of adaptation in lentil. Additional information on the specificity of adaptation within the crop has come from collaborative yield trials of common entries selected in different locations.

Understanding of genotypes and environmental factors, the local constraints to production, and the various consumer requirements of different geographic areas for seed as food and straw as feed has led the breeding program at ICARDA to develop new genetic materials for a series of separate, but finely geographically targeted streams, linked closely to national breeding programs.

The major agro-ecological regions of production of lentil are: (1) S. Asia, E. Africa, and Yemen; (2) mediterranean low-to-medium elevation; and (3) high-elevation area of West Asia and North Africa. These regions correspond to the maturity groups of early, medium, and late maturity (Table 3). Within each of these major regions, there are specific target areas. Additionally, the lentil improvement activities have recently been extended to Central Asia and Caucasus (CAC) region, where initial thrust has been put to study the adaptation and screening of diverse material suitable in their agro-climatic conditions. For Latin America, large-seed, yellow cotyledon lentils are preferred.

The lentil-breeding program generally uses parents of diverse origin with known traits with the aim to combine gene(s) to contribute to yield and resistance to major biotic and abiotic stresses. Wide crosses

Table 3 Target agro-ecological regions of production of lentil and key breeding aims

Region	*Key traits for recombination*
Mediterranean low to medium elevation	
300–400 mm ann. rainfall	Biomass (seed + straw), attributes for mechanical harvest and wilt resistance
<300 mm ann. rainfall	Biomass, drought escape through earliness and wilt resistance
Morocco	Biomass, attributes for mechanical harvest and combined resistance to rust, *Ascochyta* blight, and wilt
Egypt	Seed yield, response to irrigation, earliness, and wilt resistance
High elevation	
Anatolian highlands	Biomass, winterhardiness, and *A.* blight resistance
N. African highlands	Seed yield, low level of winterhardiness, and rust resistance
South Asia and E. Africa	
India, Pakistan, Nepal, and Ethiopia	Seed yield, early maturity, resistance to root diseases, rust, and *A.* blight
Bangladesh	Seed yield, extra-earliness and combined resistance to rust, and *Stemphylium* blight diseases
Central Asia and Caucasus	Seed yield, large-seed, good standing ability
Latin America	Large-seed, resistant to rust, and *A.* blight

among cultigens are also done by manipulating planting dates and providing 18 h extended light period to the parents to attain synchrony in flowering. In addition, crosses are made to study inheritance pattern of specific trait(s) and to develop recombinant populations for biotechnological research. More than 200 crosses are made at ICARDA every year.

Breeding Methodologies

In the early stages of lentil varietal development, most of the cultivars released were derived from selection within heterogeneous landraces. Due to increased efforts in lentil breeding at both the national and international levels, new lentil cultivars/genotypes are now being developed through cross-breeding. The methods of breeding lentil are similar to those utilized to breed other self-pollinated crops and include pure line selection or hybridization followed by the bulk method, the pedigree method, the single seed descent, or some modification of these procedures. At ICARDA a bulk-pedigree method is used, where single plant selection is done from F_4 bulks to develop F_5 progeny. A scheme of breeding methodology followed at ICARDA is given below:

1. hybridization (parent A × parent B): at Tel Hadya, ICARDA (year 1);
2. confirmation of hybridity (F_1): at summer nursery, Lebanon (year 1);
3. growing F_2 bulks: at Tel Hadya, ICARDA (year 2);
4. growing F_3 generation: at summer nursery, Lebanon (year 2);
5. growing F_4 generation: single plant selection at Tel Hadya (year 3);
6. selection among F_5 progenies for agronomic traits and *Fusarium* wilt reaction (see Figure 2): at Tel Hadya (year 4);
7. F_6 progenies are evaluated for yield, agronomic traits and *F.* wilt reaction; at Tel Hadya (year 5);
8. preliminary yield trial in F_7 at three contrasting locations: Breda, Tel Hadya (Syria) and Terbol (Lebanon);
9. advanced yield trial in F_8: at three locations except those bred for southern latitude countries; and
10. incorporation into International nurseries in F_9 generation.

The breeding program at ICARDA follows a decentralized approach. For example, in breeding for early and extra-early genotypes for southern latitude countries, targeted segregating populations are sent to the national programs to perform single plant selection in their respective edapho-climatic conditions. Similarly, selection for rust and *Ascochyta* blight resistance is done in hot spots in close collaboration with the national programs.

Understanding of Genetic Control

It is important to know the genetic control of a character before initiating a breeding program for

Figure 2 Screening against *Fusarium* wilt in lentil at Tel Hadya, ICARDA, Syria. Susceptible check and other test lines affected by the disease (in straw color).

the genetic enhancement of that particular trait. In this endeavor, various authors have studied inheritance patterns of important qualitative and quantitative traits. Information on genetic control has progressed from relatively few characterized genes in the early 1980s to the identification of major genes controlling morphological traits, isozyme loci, and DNA amplification. A list of the traits controlled by major gene(s) with their gene symbols is presented in Table 4.

Estimates of genetic parameters for traits are very useful since they provide information on the inheritance of such traits and help to identify appropriate breeding methods. Such parameters include subdivision of genetic variance into additive, dominance, and epistatis effects of minor genes. Additionally, parameters such as heritability, expected genetic gain in response to selection, and degree of association between traits are also important to design effective breeding and selection programs. In lentil, a self-pollinated species, genetic variance is expected to be primarily additive; however, the nonadditive genetic variance could also be important. Additional information on the components of genetic variance in lentil suggests that additive effects are the major component of the genetic variance for most polygenic traits and that a considerable nonadditive component can be anticipated in early generations.

Table 4 Inheritance of morphological markers

Symbol/ allele	*Character*	*Reference*
Fn	Flower number/ inflorescence	Gill and Malhotra (1980)
sn	Early flowering	Sarker *et al.* (1999)

Fw	Resistant to *Fusarium* wilt	Eujayl *et al.* (1998)
Frt	Radiation frost tolerance	Eujayl *et al.* (1999)

Again, heritability estimates are indicative of making progress through selection. Additiveness of gene action reflects in high heritability. The heritability estimates for seed yield and its components are moderate to high which indicate that good progress can be expected from effective selection. Heritability estimates for several plant traits such as plant height, lowest plant height, etc. are quite variable. Reproductive traits, such as days from sowing to flowering and to maturity, had moderate to high heritability, indicating that these traits would respond to selection. Seed quality traits such as seed size and seed thickness are strongly heritable.

Correlations between traits must be given careful consideration and interpretation by plant breeders. Correlations between seed yield and number of pods per plant, seeds per pod and secondary branches per plant, and plant height and straw yield have been positive and significant.

Evolution of National and International Breeding Programs

Lentil breeding strategy at national level and at ICARDA has changed with time. In early days, in stage 1, the variation in the germplasm collection was directly exploited. Selection was made among and within locally adapted landraces. These selections were distributed to national programs through the International Nursery Network to test for local adaptation. As a result many cultivars released by national programs are actually selections from landraces in the ICARDA germplasm collection. These stage 1 registrations emphasize: (1) the value of direct exploitation of landraces and (2) the under-exploited nature of lentil germplasm.

The particular combinations of characters required for specific regions were often not found “on the shelf” in the germplasm collection. Consequently,

ICARDA started hybridization and selections from segregating populations were made at ICARDA in Syria to produce stage 2 material. Such selections were then distributed after multiplication to the national programs to select in their respective agroclimatic conditions. This has resulted in the release of a number of cultivars in different regions.

However, lentil lines developed from selection at ICARDA in West Asia are mostly limited to adaptation to the home region. As a result, the breeding program has decentralized to work closely with national programs. For the other regions, at stage 3, crosses are agreed upon with national level cooperators and then made at ICARDA, Tel Hadya, Syria, and then country-specific segregating populations shipped to national cooperators for local selection. Selections made by national programs are then fed back into the International Nursery Network for wider distribution.

In stage 4, the national programs directly use ICARDA-derived material in hybridization and selections are made locally.

Developments in Biotechnology

Biochemical and molecular techniques have been used for biodiversity evaluation, assessment of the genetic structure of natural populations, plant systematic and evolution in the genus *Lens* summarized by Ferguson and Robertson, Abo-elwafa, Sharma *et al*. Major investigations were carried out with allozymes, seed protein cDNA and genomic DNA RFLPs, chloroplast DNA RFLPs, and RAPD analysis of genomic DNA. Even though discrimination between lines is possible, seed proteins have not been extensively used for genetic diversity studies.

Establishing linkage maps for agricultural crops is to localize gene(s) for important agronomic traits and to develop tightly linked morphological and molecular and markers to enable indirect selection by marker assisted selection. The earlier linkage maps covered a small number of markers. With the advancement of classical genetics and molecular research, a more comprehensive linkage map for lentil genome spanning more than 1073 cM has been developed.

Qualitative traits such as epicotyl color, seedcoat pattern or spotting, pod indehiscence, etc. have been localized, and linked DNA markers have been identified. Quantitative traits in recombinant inbred lines of interspecific crosses have been localized with isozyme markers. Detected quantitative trait loci (QTLs) were located in six of the seven chromosomes. Abbo *et al*. studied the genetics and linkage of seed weight and observed QTLs affecting seed weight were associated with morphological and RAPD-markers, which were distributed over several linkage groups. Recently, one major and two minor QTLs were detected for winter-hardiness.

Major Achievements

Varietal Releases by National Programs

ICARDA supplies nurseries to national programs comprising a range of genetically fixed materials and segregating populations to select according to their specific needs. On the basis of phenological adaptation, agronomically desirable traits, resistance to prevailing stresses, quality aspects, farmer's and consumer's preference, etc., national scientists identify and select promising lines/single plants for eventual release for commercial cultivation. In this endeavor, to date 77 lentil varieties have been registered by 29 countries for improved yield, disease resistance, and other traits (Table 5).

One of the major achievements is the breaking an ancient bottleneck of narrow genetic base of lentil in South Asia, which produces nearly half of world's lentil. Genetic base was broadened through introgression of genes from ICARDA in the region. Early, high-yielding and disease-resistant varieties have been released in Bangladesh. High-yielding varieties with combined resistance to fungal diseases have been

Table 5 Lentil varieties emanated from ICARDA-supplied materials released by the National Agricultural Research Systems

Region	*Country*	*No. of varieties*	*Reason*
Asia	Bangladesh, India, Nepal, Pakistan, China, Afghanistan, Iran, Iraq, Syria, Lebanon, Jordan, Yemen, Turkey	37	High yield; wilt, rust and *Ascochyta* blight resistance; good standing ability, resistance, high biomass, early maturity, winterhardiness
Africa	Ethiopia, Egypt, Morocco, Libya, Tunisia, Algeria, Lesotho, Sudan	26	High yield; wilt and rust resistance; early maturity; tolerance to excess moisture
The Americas	Argentina, Canada, Ecuador, USA	6	High yield; rust and *A.* blight resistance; good standing ability
Oceania	Australia, New Zealand	9	High yield; *A.* blight resistance; good standing ability
Europe	Portugal	2	High yield
Caucasus	Georgia	1	High yield

released in Pakistan. Extra-early and extra-bold lines have been developed in India to fit in different cropping system niches. Medium maturing cultivar, Shekher (ILL 4404), is being cultivated in mid-hills in Nepal, a new lentil area.

Ethiopia and Morocco released rust resistant varieties, spreading very fast among the farmers. In West Asia, wilt resistant varieties provide momentum in lentil cultivation. All Australian varieties covering an area of 125 000 ha were from direct selection from ICARDA germplasm.

Reconstruction of Genotypes Suitable for Mechanization

To keep lentil in the cropping system by reducing cost of production in West Asia, it is essential that lentil harvest be done mechanically. With more urbanization there has been a tremendous shortage of agricultural labor in this region. This led to a rapid rise in the cost of hand labor, and the total lentil production cost goes up tremendously.

In order to address this constraint and encourage the expansion of the environmentally sustainable legume-cereal rotation in the dry areas, during its first decade ICARDA made a major drive to develop economic machine harvest systems for lentil cultivation. Following the introduction and use by farmers in Syria and Turkey of such systems, a moratorium was placed on further technical research at ICARDA. The Center has developed and promoted a lentil production package that includes mechanization and the use of improved cultivars with good standing ability. Joint ICARDA–NARS breeding programs have produced new varieties suitable for mechanical harvesting – such as "Idlib-1" and "Idlib-2" in Syria and "Sayran 96" in Turkey. On-farm trials and demonstrations have verified the value of the mechanization package. On average, mechanical harvesting combined with improved cultivars reduces harvest costs by 17–20%.

Future Challenges

Exciting gains in sustainable production arise from the integration of a change in agronomic practice with a new cultivar. Several such prospects exist for lentil and are given below.

In highlands West Asia, lentil is currently spring sown. However, sowing in late autumn/early winter coupled with the use of a winterhardy cultivar gives yield advantages of ~50%. Although agronomic constraints to winter-sowing lentil in the Highlands require further research, this substantial yield increase can be expected in the future to augment the area and production in this agro-ecological zone.

In the some areas around the Mediterranean, such as in south Syria, lentil production has ceased primarily because of vascular wilt disease. The registration of *Fusarium* wilt-resistant cultivars Idlib-2′ in Syria and "Rachyy" and "Hala" in Lebanon offers the prospect of a return of lentil cultivation to such areas. Further spread of lentil harvest mechanization technology will probably also contribute to increased lentil production in West Asia in the future.

In South Asia, the diseases wilt, rust, and *Ascochyta* blight are key problems and large areas are left fallow over winter following the harvest of late paddy rice. Farmers need early maturing, disease-resistant varieties with late sowing potential for such situations or when land becomes available for lentil planting after the monsoon floodwaters have subsided. As extra-early maturing cultivars with combined resistance to diseases become available, the prospect will open of a major expansion of lentil production in the rice-based cultivation system in the Indian subcontinent.

Molecular tagging of genes responsible for resistance to biotic and abiotic stresses needs to be done to assist breeding program. Further, research on functional genomics to address some of the key problems should be initiated.

Introduction

Lentil (*Lens culinaris* Medik) is one of the world's oldest crops having been cultivated in southwestern Asia since 7000 BC. The crop is best adapted for production in temperate climates but is now produced in different parts of the world. India is the world's leading consumer of lentil and the second leading producer. In North America, the United States of America (USA) and Canada are the main producers of lentil. Lentil has been grown commercially in the Palouse region of eastern Washington and northern Idaho since the late 1930s. Lentil production in Canada began in 1969, and currently Canada is the leading lentil producer and exporter. Turkey and Australia are major exporters of lentil. Other important lentil-producing countries include Syria, Ethiopia, Argentina, and Chile.

Agronomic requirements for lentil differ from region to region depending on the climatic conditions, cropping system, and variety. In Canada, USA, the highlands of Turkey, and Iran, lentil is grown in spring on conserved moisture. In the Indian subcontinent, it is grown using soil moisture from the preceding monsoon season supplemented with infrequent winter rainfall. Lentil is also raised in winter in Australia and the lowlands of Turkey and Syria. In each of these growing environments, agronomic practices have been developed to suit climatic and soil conditions, and the predominant lentil varieties.

Description of Lentil

The lentil is an annual herbaceous plant with a slender stem and branches. Plant height ranges from 20 to 75 cm. Lentil plants have indeterminate growth habit, continuing to flower and to produce pods until moisture, nutrient deficiency or temperature stresses occur.

Lentil is classified into two types based on seed size. "Macrosperma" or Chilean lentil has large seeds of ~6–9 mm in diameter (mass greater than 50 g/1000 seeds). "Microsperma" or Persian lentil has small seeds of ~2–6 mm in diameter (mass 40 g or less/1000 seeds). Seeds of both types are generally lens-shaped but some microsperma types have rounder seeds. The seedcoat may be red, green, gray, brown, black, or mottled. Cotyledons may be red, yellow, or green (*see* **Lentil**: Breeding).

Adaptation and Land Requirement

Lentil is a cool season or temperate crop. The optimum temperature for growth is 18–24°C. The crop has moderate tolerance to drought or high temperatures. In some regions such as southeastern Turkey and Australia, lentil is a winter crop sown in autumn and maturing early in summer. The crop will not tolerate extremely cold, dry winters. Currently, work is under way in USA, Turkey, and the International Center for Agricultural Research in the Dry Areas (ICARDA) in Syria to improve the winterhardiness of the crop. Lentil plants are sensitive to waterlogging and will not tolerate flooding or salinity. Water requirement for optimum lentil yield varies from region to region depending on the rate of evaporation. Wet weather during the reproductive period of crop growth can delay maturity, reduce seed set, and increase susceptibility to foliar diseases.

Lentil is adapted to a wide range of soil types. In India, lentil is grown on different soil types ranging from heavy clay to loamy sands. In the Mediterranean region and in North Africa, fields of varying slope, soil texture and depth are used for lentil production. In southwestern Australia, lentil is grown in well-drained, neutral to alkaline loam, and clay loam

soils. Lentil can be grown from slightly acidic (pH 5.5–6.5) to moderately alkaline soil (pH 7.5–9.0).

Land Preparation and Rotations

Land preparation required for lentil production varies depending on soil type and cropping system. Lentil can be grown under conventional, minimum till or zero till production systems. In the Indian subcontinent and parts of the Mediterranean region, land preparation is usually minimal to conserve moisture. In Africa, land is deep-plowed followed by cultivation with a disc harrow. In USA, autumn-chisel plowing is used to increase water infiltration, decrease erosion, and maximize retention of crop residues in fields intended for lentil production. Tillage in spring is kept minimal. In western Canada, grain yields and net returns for lentil grown on stubble using zero or minimum till are higher than those from conventional tillage systems. Tall stubble reduces soil moisture evaporation resulting in greater water-use efficiency and increased lentil yield. Tall stubble also increased pod clearance making combining or swathing easier and reducing pod shattering.

Throughout the world, the lentil crop is often grown in rotation with cereals. In India, lentil is generally grown in a double-cropping system following a monsoon-season crop of maize, sorghum, jute, or rice. The lentil crop is grown following a fallow where the monsoon rains are low. In eastern India and Nepal relay cropping is practiced with the lentil crop planted in a standing crop of paddy rice, when the rice crop is close to maturity. Multicropping is practiced under the humid subtropical conditions at the foothills of the Himalayas. For example, triple cropping of jute–rice–lentil has been found to be more productive than a double cropping of either jute–lentil or rice–lentil.

In the Mediterranean region, North Africa, parts of Ethiopia, Eastern Europe, and North America, lentil is generally a component of a two-to-four course rotation incorporating cereals and forages. Lentil, like other pulses, is an important component of these rotations with advantages extending beyond the year in which the lentil is grown. Pulse crops improve the soil tilth, diversify the rotation, and increase the availability of nitrogen and soil organic matter. Pulse crops break the cereal-disease cycles resulting in low-disease pressure in cereal crops following pulse crops. Table 1 shows the performance of a wheat crop following either lentil or another wheat crop. Seed yield, straw yield, seed N yield, straw N yield, and disease severity were lower in the lentil–wheat rotation than in the wheat–wheat rotation.

Seeding

Lentil can be seeded with a wide range of seeders ranging from hoe drills to air seeders. Like other pulse crops, lentil seed is very susceptible to damage during seeding; hence, it is important to handle seed carefully especially when using air seeders. Airflow should be kept at low speed and seed moisture should be kept at 14% minimum.

The rates of seed germination, seedling emergence, and growth are sensitive to temperature. Optimum germination for most lentil varieties occurs at 15–25°C. As temperature decreases, the germination process slows down. A seeding depth of 4–5 cm is recommended for good germination and growth.

Seeding Rates

Recommended seeding rates for lentil vary from 40 kg ha^{-1} to as high as 160 kg ha^{-1}, depending on growing conditions and lentil variety. These rates are based on target population densities for the growing environment and should be adjusted for germination. Seeding rates of 40 kg ha^{-1} are recommended for small-seeded lentil under Indian conditions. In west Asia and the Mediterranean region, seeding rates of 60–80 kg ha^{-1} for small-seeded lentil and 120–160 kg ha^{-1} for large-seeded lentil are recommended. Studies conducted recently in Mediterranean-like environments of southwestern Australia recommend a target population density of 150 plants m^{-2} by using a sowing rate of 90–110 kg ha^{-1}. In USA

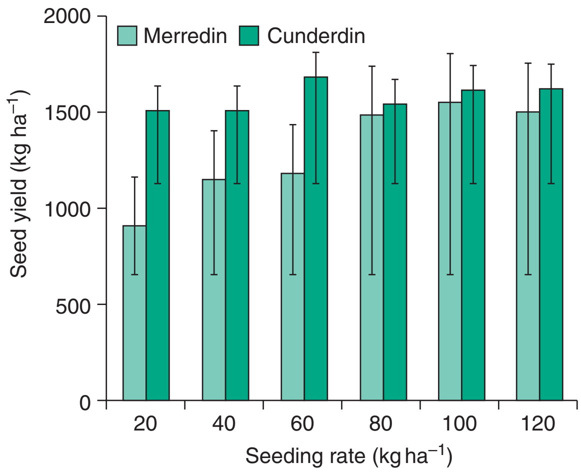

Figure 1 Effect of seeding rate on seed yield of lentil at Merredin and Cunderdin in southwestern Australia in 1996. Vertical lines are standard errors. (Adapted from Siddique KHM, Loss SP, Regan KL, and Pritchard DL (1998) Adaptation of lentil (*Lens culinaris* Medik) to short season Mediterranean-type environments: response to sowing time. *Australian Journal of Agricultural Research* 49: 1057–1066.)

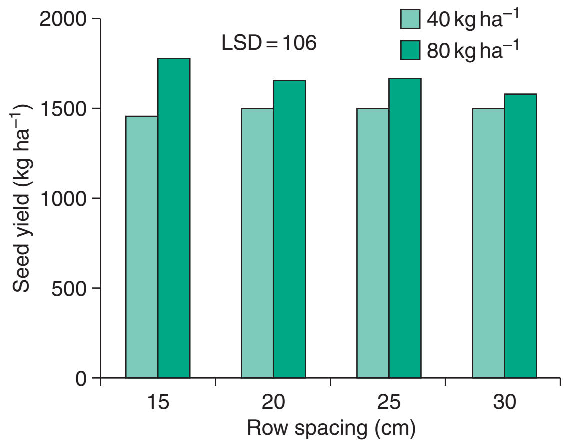

Figure 2 Effect of row spacing and seeding rate on seed yield of lentil line ILL-4401 at Tel Hadia, Syria, 1977–78. (Adapted from Saxena MC (1981) Agronomy of lentils. In: Webb C and Hawtin G (eds.) *Lentils*, pp. 111–129. London: Commonwealth Agricultural Bureau)

recommended seeding rates for Palouse growers are 67–79 kg ha^{-1} based on a target plant density of 90 plants m^{-2}. In western Canada the target density is 130 plants m^{-2} and recommended seed rates range from 45 to 90 kg ha^{-1} depending on variety.

Some research shows that lentil yield is stable over a range of population densities while other studies report a general trend towards yield increase with increase in seeding rate. Differences in lentil varieties used, as well as growing conditions the crop is subjected to, can affect the response to seeding rate. For example, Figure 1 shows the effect of the growing environment on lentil seed yield response to seeding rate in southwestern Australia in 1996. In a dry environment like Merredin (mean growing season rainfall = 212 mm) lentil seed yield increased with increase in seeding rate, whereas in a wetter environment like Cunderdin (mean growing season rainfall = 274 mm), seed yield was relatively stable over a wide range of seeding rates. This indicates the limited ability of lentil plants to compensate for low density in dry environments. Compared to some other pulse crops, a lentil plant is small and has a more determinate growth habit. Higher plant population densities are required for early maturing lentil varieties compared to full-season lentil varieties that tend to have larger plant type.

Optimum row spacing depends on lentil variety and cropping system. Differences in lentil performance due to row spacing are more obvious in dry environments than in environments with adequate soil moisture. In narrow row spacings, the crop canopy closes faster reducing loss of water by soil evaporation. However, it is the combination of plant density used with a particular row spacing that determines the performance of the lentil crop in a particular environment as shown in Figure 2. In a wet year in Syria, narrower row spacings combined with higher seeding rates gave greater lentil seed yield compared to wider row spacings with low or high seeding rates.

Broad-leaf weed management for the lentil crop is a serious problem wherever lentil is grown. In some environments, high seeding rates have suppressive effects on weeds. Using high plant densities and narrow rows is not advisable in wet environments, the thicker canopy may facilitate rapid spread of foliar diseases.

Time of Seeding

The optimum date of seeding lentil varies from region to region. In all regions where lentil is grown, seed yield can be optimized by timing sowing such that crop development and growth occurs when climatic variables such as rainfall and temperature are favorable. In USA and Canada, lentil is usually seeded in early spring. Seeding begins as soon as the soil temperature at the seeding depth is ~5°C. This usually occurs in late April to early May but wet conditions sometimes delay seeding. In western Canada, the yield advantage due to early seeding is substantial and the decrease in seed yield due to delay in seeding differs from one environment to the next. Figure 3 shows that the decrease in lentil yield with delay in seeding is more drastic at Swift Current (mean annual precipitation = 350 mm) a semiarid environment with light-textured soils but that yield decrease is more gradual at Melfort (mean annual precipitation = 409 mm)

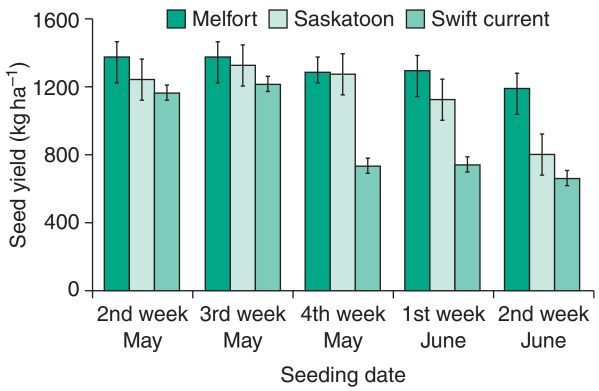

Figure 3 Effect of seeding date and location on the seed yield of lentil. Vertical bars are standard errors. (Unpublished data: Nleya T, Gan Y, Vandenberg A, and Kutcher R (2003) Lentils for the Next Century: Diversification of Red Lentil Production Systems for Saskatchewan.)

a cool moist environment with heavier-textured soils. Saskatoon with intermediate conditions in terms of soil moisture and soil type showed a decrease between the two extreme locations. In southwestern Australia, a reduction in seed yield with delayed seeding as high as 4–29 kg ha^{-1} day^{-1} has been reported. A reduction in seed yield due to delay in seeding has been observed throughout most lentil growing regions in the world irrespective of the climatic conditions. This is because early sowing allows for an extended period of vegetative and reproductive growth.

In areas with mild winters such as west Asia and southwestern Australia where lentil is grown as a winter crop, early autumn seeding has advantage over late autumn or spring seeding. In temperate climates like in Canada, severe winter temperatures reduce plant density and yield for the autumn-seeded lentil crops compared to spring-seeded lentil crops (Table 2).

Fertilizer Requirements

Lentil plants have high demand for plant nutrients. Lentil accumulates the maximum amount of nitrogen (N), phosphorus (P), and sulfur (S) in the seed; hence, a considerable amount of each of these nutrients is exported with the seed at harvest. Adequate application of the essential macronutrients including P, potassium (K), and S is necessary for good yields. Nitrogen is supplied via biological N fixation, mineralized soil N, or N fertilizers, or a combination of these sources. The best way to determine nutrient requirements is by soil tests.

Under good conditions for symbiotic association, 70–90% of the N requirement for the lentil crop can be met through biological N fixation, with the remainder derived from soil N sources. Thus, a well nodulated lentil crop inoculated with an appropriate lentil rhizobium will generally not respond to the application of inorganic N fertilizer. Lentil growing in soils with low organic matter, in dry environments or seeded early into cool, wet soils may benefit from the application of low rates of N as a "starter N" source. However, because high levels of inorganic N are known to have adverse effects on early nodulation or will delay nodulation leading to poor seedling growth, starter N application rates should be limited to 10–25 kg ha^{-1}. Starter N rates greater than these amounts may encourage excessive vegetative growth and prolonged maturity, both of which lead to poor seed set. In wet conditions, too much vegetative growth may create a microclimate suited for disease development.

Adequate P nutrition is essential in lentil production for optimum N fixation, optimum seed yield and for the crop to mature in time. Phosphorus enhances root development and improves the ability of a lentil crop to tolerate stresses such as drought and frost. Although lentil has a relatively high requirement for P, seed yield responses to P fertilizer application are not consistent, even in soils low in available soil P. Moreover, responses to P fertilizer application are related to environmental factors, with greatest responses typically occurring in cool, wet soils.

Lentil seed is very sensitive to seed row applied P fertilizer and a significant reduction in plant stand and seed yield can occur at high P levels.

Small amounts of P (~20 kg ha^{-1} based on a narrow seed row at 15 cm spacing) placed with the seed may not be harmful and the adverse effect on plant stands may be more severe under drier soil conditions. Where P fertilizer application is necessary banding the fertilizer to the side away from the seed is recommended.

Lentil has a high need for K, requiring ~4.7 kg K_2O for every 100 kg seed produced. However, response to K generally is limited to soils with a low capacity to supply K, such as sandy soils. Like P, K moves by diffusion in the soil; hence, soil temperature and moisture can influence movement and availability to plants.

Sulfur-deficient soils can limit yield of lentil. Plants deficient in S show yellowing from the top downwards, symptoms that are sometimes confused with N deficiency. The distinguishing feature is that with S deficiency top leaves yellow first. To correct S deficiency in the cropping system a sulfate form of S fertilizer must be used. Annual application of elemental S can be used to build S in the soil but will not be available to the crop in the year of application.

Researchers are uncertain of micronutrient requirements for productive lentil crops. Limited research has shown that deficiencies in zinc (Zn), molybdenum (Mo), and boron (B) may occur in lentil production.

Zinc deficiency occurs on alkaline soils and is widespread in soils used for paddy rice production in India, Nepal, and Pakistan where lentil grown after paddy rice has shown response to Zn fertilizer application. Zn deficiency can be corrected by soil application of zinc sulfate or foliar spray of zinc sulfate at the first appearance of deficiency symptoms.

Lentil, like other legume crops, requires Mo for the N fixation process. Mo deficiency is likely to occur in soils with pH lower than 5.6. Low levels of Mo in soils can cause poor growth and limit yield of lentil. Leaves of lentil deficient in Mo are chlorotic and plants are stunted. The Mo-deficiency symptoms are difficult to distinguish from N- and S-deficiency symptoms. Liming and application of P fertilizer can reduce the severity of Mo-deficiency in lentil growing in Mo deficient acid soils. Since Mo concentrations in soils are small and difficult to detect, fertilizer recommendations are often based on cropping history and soil pH. Mo fertilizer can be applied to the lentil crop as a seed treatment or a foliar spray.

Soils which are acidic, coarse-textured, and have low organic matter tend to be deficient in B. Boron deficiency has been observed in lentil fields in northwestern USA and in acidic nutrient-deficient soils in Nepal. Differences in B efficiency have been observed in lentil genotypes and seem to be associated with geographical origin. Boron deficiency in lentil can be corrected by broadcasting B fertilizer. It is important that B requirements be determined by soil tests and that recommendations be followed when applying B fertilizer. Boron can be toxic to plants if higher concentrations are applied or if applied too close to seedlings. Boron toxicity problems have been reported in some regions of Australia.

Weed Management

Lentil seedlings grow slowly early in the growing season, and at this stage the crop competes poorly with weeds for light, water, and nutrients. Weeds are particularly a problem in temperate climates where the cool weather at seeding time slows down the germination process and weeds can quickly overgrow the crop. Weed control in lentil therefore requires a long-term strategy involving different methods of control and proper crop rotations.

Preventative measures such as diversified crop rotations and tillage are an important part of long-term management strategy. Growing different crops in different years allows for use of different weed management options. Both the date when tillage is done and the kind of tillage have important implications on weed prevention. In temperate climates for example, autumn and spring preseeding tillage is used to control biennial and annual weeds. Preseeding spring tillage should be early enough to allow weed emergence and control before seeding the lentil crop. Where weed seeds are buried deep, shallow tillage can be used to avoid bringing weed seeds close to the surface where they can germinate.

Post-emergence harrowing is generally not recommended because this method can damage seedlings and increase incidence of root and stem diseases. Whenever this method is used it is important that the crop be short, and that the foliage is dry and that operation be conducted on a warm sunny day.

Handweeding with a hoe or hand pulling is a traditional method of weed control and is still practiced in lentil production in countries such as India, North Africa, and West Asia. The number of weedings required depend on climatic conditions and weed infestation level.

Only a limited number of herbicides are registered for use in lentil worldwide. Different herbicides are used to control weeds in lentil in different regions of the world. In USA and Canada Metribuzin™ is registered for the control of broad-leaf weeds pre-emergence and post-emergence. Trifluralin™ is applied in the autumn to control both grass and broad-leaf weeds in western Canada. In Australia and New Zealand, successful weed control in lentil has been achieved by using Trifluralin™ presowing, Cyanazine™ pre-emergence and Metribuzin™

post-emergence. Glyphosate™ can be used as a pre-emergent burn-off treatment to control weed before crop emergence and is also registered for preharvest weed control in lentil. Herbicide users should follow labels for recommended application time, rates, and precautions to be taken.

Diseases

Lentil is affected by many diseases caused by fungi and viruses. Major diseases caused by fungi include the seedling blight/root rot complex, wilt, sclerotinia stem and pod rot, botrytis stem and pod rot, rust, *Ascochyta* blight, anthracnose, and stemphylium blight. The most important seedling blight and root rot diseases are caused by *Pythium*, *Rhizoctonia*, and *Fusarium* species. *Pythium* causes the damping-off of seedlings while *Fusarium* results in root rot. Symptoms include lesions and discoloration at the base of the stem. Diseased plants turn yellow and eventually die. Root rots and seedling blights occur in patches in lentil fields and rarely cause economic losses unless they are associated with other diseases (**Table 3**).

Wilt caused by *Fusarium oxysporum* f. sp. *Lentis* is a serious disease in most lentil growing areas of the world (Figure 3). The disease may appear as seedling wilt in the early stage of crop growth or as adult plant wilt during reproductive growth. Symptoms are first seen as sudden drooping of leaflets starting at the top of the plant and then progressing downward. This is followed by shriveling of leaves and wilting of the whole plant. Wilt occurring at flowering will lower seed production whereas wilt appearing during the pod filling period will reduce yield drastically.

Sclerotinia caused by *Sclerotinia sclerotiorum* (Lib.) de Bary, causes stem and pod rot. Symptoms include necrotic lesions, which eventually produce white mycelial growth. The fungus overwinters as soil-persistent sclerotia. Botrytis stem and pod rot, caused by *Botrytis cinerea* (Pers.:Fr), is another disease commonly found on lentil crops in temperate climates. Symptoms include necrotic lesions on stems and pods with gray sporulating mycelial growth. Both these diseases are of major concern when the crop experiences high humidity after full canopy closure and is susceptible to lodging. Including cereal crops in a rotation can reduce the buildup of inoculum of soilborne pathogens.

Rust caused by *Uromyces viciae-fabae* is an important disease of lentil in areas with mild temperatures and humid conditions. It has been reported in many lentil-growing countries including India, Turkey, Iran, Morocco, and Ethiopia. Rust has not been reported in lentil in North America. The disease affects all aerial parts of the plants and symptoms include yellowish-white pycnidia and aecial cups on the lower surface of leaflets and pods. Uredia then form on either side of leaflets, stems, and pods. Where infection is severe, lentil plants can die before maturity. The disease is spread from inoculum arising from infected plant material usually mixed with seed. Lentil genotypes with some resistance to rust are now used in breeding programs where rust is a serious problem. (*see* **Lentil**: Breeding).

Ascochyta blight, caused by *Ascochyta lentis* (Vassil.) is a serious disease of lentil in many parts of the world, particularly Canada, Australia, and Pakistan. The disease can be seed- or residue-borne. The symptoms include gray to tan lesions on leaves, stems, pods, and seeds. The lesions have dark margins and may have pycnidia in the centers. Under severe infection, leaves turn completely brown and drop and the infected seed is discolored. The fungus can overwinter on lentil stubble in the field. While wind movement of spores from one field to the next is limited, this can happen in adjacent fields. Seed-borne *Ascochyta* can be treated by using fungicidal seed treatment. The effectiveness of seed treatment depends on the level of infection and on environmental conditions. As low as 1% seed infection can result in severe epidemics in cool, moist conditions, whereas as high as 5% seed infection may not cause severe problems in dry years.

Table 3 Major fungal diseases of lentil

Disease	*Causal organism*	*Favorable climatic conditions*
Root rot/seedling rot	*Pythium* spp. *Rhizoctonia* spp. *Fusarium* spp.	Wet, cool conditions at seeding
Wilt	*Fusarium oxysporum*	Moderately high soil temperatures (20–25°C), sunlight
Stem and pod rot	*Sclerotinia sclerotiorum*	Wet conditions, dense canopy
	Botrytis cinerea	Late season
Rust	*Uromyces viciae-fabae*	Mild temperature, humid conditions
Ascochyta blight	*Ascochyta lentis*	Cool (15–20°C), wet conditions
Anthracnose	*Colletotrichum truncatum*	Warm (20–24°C), humid conditions
Stemphylium blight	*Stemphylium botryosum*	Warm, wet conditions

High levels of *Ascochyta* can cause losses in yield and quality of lentil. Foliar fungicides such as chlorothalonil are available for controlling the spread of *Ascochyta* blight in lentil. Genetic sources of resistance are available and are being deployed in breeding programs (*see* **Lentil**: Breeding).

Anthracnose caused by *Colletotrichum truncatum* (Schwein.) is a fungal foliar and stem disease of lentil. It has been reported in western Canada where it can cause significant yield losses. Symptoms include gray to cream spots on leaves and stems, yellowing and browning and eventually senescence. The disease spreads rapidly in the field and can be spread on wind-borne chaff and dust during harvest. Anthracnose inoculum can also be carried over in crop residues as sclerotia in the field for several years. The level of seed-to-seedling transmission of anthracnose is low. Treating infected seed with fungicides to control seed-borne anthracnose is not important, but use of disease-free seed can help to minimize the spread of the pathogen in the field. To reduce levels of field inoculum, it is important to ensure that lentil is not planted in the same field for at least 4 years. Foliar fungicides, e.g., chlorothalonil, are available to control anthracnose in lentil. Good timing of application is critical for effectiveness of the fungicides.

Stemphylium blight caused by *Stemphylium botryosum* is a foliar disease of lentil in Canada and Bangladesh. Infected plants suffer leaf drop and premature ripening. The epidemiology of this disease is not well understood. Some sources of genetic resistance are available and they have been used in Bangladesh to control the disease.

Viral diseases of lentil include alfalfa mosaic, bean yellow mosaic, bean (pea) leaf roll viruses (BLRV), pea enation mosaic virus (PEMV), and pea streak. Some of the viruses can be seed-borne while others are transmitted by aphids, white fly, and other insects. The best control method for viral diseases is use of resistant lentil varieties.

Insect Pests

A wide range of insect pests attack the lentil crop wherever it is grown. Crop losses to insect pests tend to be sporadic and dependent on insect population. Insects that are of economical importance in lentil include aphids (*Aphis* spp.), lygus bugs (*Lygus* spp.), cutworms (*Agrotis* spp.), bruchid beetles (*Bruchus* spp.), lepidopteran pod borers (*Helicoverpa* spp.), and grasshoppers. Cutworms feed on stems and roots of seedlings, whereas aphids and lepidopteran larvae attack leaves stems and flowers. Lygus bugs and bruchid beetles damage pods and seeds. Grasshoppers primarily eat flowers and pods.

Insect pests are controlled by following an integrated pest management system. Awareness of the biology of the insects likely to infest lentil in the region, is the key to knowing when to scout for insects to minimize infestation by agronomic techniques. Natural enemies may be used to keep populations of some insects below economic threshold. Insecticides are available for controlling major pests in lentil. These should be used when necessary and with caution.

Harvesting

In many lentil-producing areas of western Asia, Africa, and India, harvesting is traditionally done by hand. In many countries the chaff and straw are valuable animal feed. Mechanization of lentil harvest has been one of the main objectives of national and international research programs throughout the world. At ICARDA, breeders are developing tall, nonlodging lentil varieties with nonshattering pods to suit mechanical harvesting systems. Mechanical harvesting devices to suit these production systems are also being developed.

Mechanized harvesting is practiced in South America, North America, Australia, New Zealand, and parts of Europe. In these countries combine harvesters are used either to directly combine the crop or to swath the crop and leave it in windrows to dry. The dry plants are then picked and threshed with combines. Rolling of the seedbed to level the soil surface after seeding makes it easier to harvest pods held close to the ground. Rolling also reduces cutterbar damage and speeds up swathing or direct combining. Cutting or swathing is done when ~30% of lower pods have turned tan and the seed rattle. Recommendations are that swathing be done in the morning when humidity is high to minimize pod shattering. Lentil is combined within 2 weeks of swathing.

Acknowledgment

The authors would like to thank Dr. Godfrey Chongo for reviewing the disease section.

LIPID CHEMISTRY

L Day, Food Science Australia, Werribee, VIC, Australia

Introduction

After protein and carbohydrate, lipids (commonly know as fats or oils) are the third most important macronutrient in human and animal diets. Although lipids are relatively minor constituents in cereal grains, they play a significant part in quality changes during grain storage, and in most aspects of processing, including milling, brewing, baking, and extrusion. On the other hand, oilseeds are primarily grown for their oil content. The composition of the lipids (or oil) in various oilseeds is therefore an essential consideration in determining the use of the oil, and the lipids are important for the maintenance of health.

This article is intended to give a general overview of lipid composition in cereal grains and oilseeds, their extraction and identification, their importance in cereal technology, and the nutritional values of edible oils.

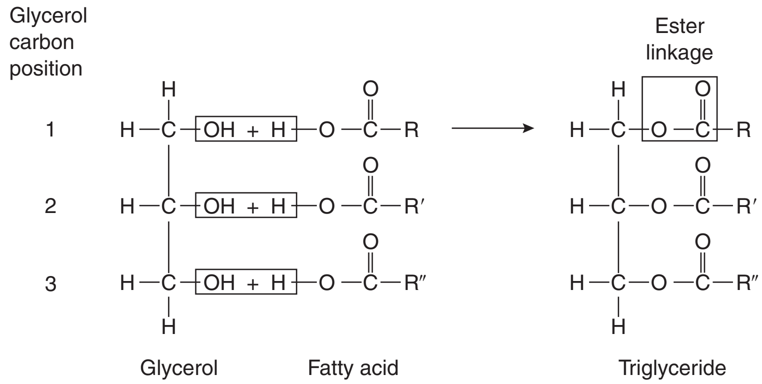

Figure 1 Triacylglycerol synthesis: *R*, *R′*, *R″* are usually long-chain alkyl groups and *R*, *R′*, *R″* are typically all different and may also contain one or more carbon–carbon double bonds.

Nomenclature and Classification

Lipids constitute a wide variety of naturally occurring substances in plant and animal tissues. They are generally insoluble in water; soluble in organic solvents such as ether, chloroform, and alcohols; and contain long-chain hydrocarbon groups in their molecules.

Lipids can be classified based on their physical properties at room temperature – oils are liquid and fats are solid; the polarity-neutral lipids include fatty acids (FAs), glycerides and sterols, and polar lipids include glycerophospholipids (phospholipids) and glyceroglycolipids (glycolipids). The most common classification of lipids is based on their structure – simple or complex. Simple lipids, composed of FAs and alcohol components, include acylglycerols, ether acylglycerols, sterols, and their esters that can be hydrolyzed to two different components – usually an alcohol and an acid. Complex lipids include phospholipids, glycolipids, and sphingolipids, which yield three or more different compounds on hydrolysis.

The fatty acids (FAs), i.e., carboxylic acids, are the main building blocks in lipid structures. Only a small portion of the total lipid fraction consists of free carboxylic acids, or free fatty acids (FFAs). Most of the carboxylic acids in the lipid fraction are found as esters of glycerol, i.e., as triacylglycerols (TAGs), commonly known as triglycerides (Figure 1).

The most common TAGs are those with long-chain carboxylic acids (C_{14}–C_{22}). Positions of carboxylic acids in TAGs are very important to their properties and utilization. The saturated forms of FAs are the most stable against oxidation and they also have high melting points in comparison with unsaturated FAs with the same number of carbon atoms. In plant TAGs, unsaturated fatty acids are predominantly located in the 2-positions. Monoacylglycerols (MAGs) contain only one long-chain FA (saturated or unsaturated) at either the 1, or 2, or 3 positions. Similarly diacylglycerols (DAGs) have two FA chains at any of the two positions. However, the phosphoric acid residue of phosphoglycerides (PLs) and the first glycosidic residue of glycosylglycerides (GLs) are always in position 3. The general classification of principal lipids found in cereal and oilseeds, brief descriptions of their basic structure, and their common abbreviations are listed in Table 1.

Compositions and Distribution of Lipids in Cereals and Oilseeds

Cereal Grains

Lipids are minor components of the cereal grains (**Cereals**: Overview). Wheat, barley, brown rice, rye, and sorghum have lower lipid contents than other cereal crops such as oats, pearl millet, and maize. All cereal grain lipids are richer in nonpolar lipids than in polar lipids. Wheat contains the highest level of glycolipids among all cereal grains, followed by triticale, rye, and barley. Millet, maize, and sorghum lipids contain the lowest glycolipid content. In general, phospholipids also are more abundant in wheat, triticale, and rye lipids and slightly lower in the lipids of barley, maize, oat, sorghum, and rice. Approximate lipid contents and the proportions of nonpolar lipids and polar lipid (separated into glycolipids and phospholipids) in each cereal are listed in Table 2.

TAGs are the major nonpolar lipids in cereal grains, representing from ~50% of total nonpolar lipids in wheat and barley to as high as 90% in maize. They are deposited in spherosomes (oil droplets) bound by a monolayer membrane and are usually stored by plants in this form. The remainder of the nonpolar lipids are mainly di- and monoglycerides, FFAs, and sterol esters. The major phospholipids in cereal grains are phosphatidylcholine (PC),

Table 1 General classification of lipids and their commonly used abbreviations

Lipid class	*Abbreviation*
Simple lipids: compounds with two types of structural moiety	
Glyceryl esters: esters of glycerol and fatty acids (see Figure 1)	
Triacylglycerols: 3 × fatty acids	TAGs
Diacylglycerols: 2 × fatty acids at any 2 positions	DAGs
Monoacylglycerols: 1 × fatty acid at any position	MAGs
Sterol esters: esters of sterol and fatty acids	SE
Waxes: esters of long chain alcohols and fatty acids	
Complex lipids: compounds with more than two types of structural moiety	
Phospholipids: glycerol esters of fatty acids, phosphoric acid and other groups containing nitrogen	
Phosphatidic acid: diacylglycerol esterified to phosphoric acid	
Phosphatidylcholine: phosphatidic acid linked to choline	PC
Phosphatidylethanolamine	PE
Phosphatidylserine	PS
Phosphatidylinositol	PI
Lysophosphatidyl-choline, -ethanolamine, -serine, -inositol	LPC, LPE, LPS, LPI
Glycoglycerolipids: 1,2-diacylglycerol joined by a glycosidic linkage through position *sn*-3 to a carbohydrate moiety	
Monogalactosyldiglyceride	MGDG
Digalactosyldiglyceride	DGDG
Monogalactosylmonoglyceride	MGMG
Digalactosylmonoglyceride	DGMG

Table 2 Approximate lipid contents and the distribution of lipid classes of the total lipids in cereal grains

Cereal grains	*Total lipids (% w/w in whole grain)*	*Lipid class (% w/w of TL)*		
		NL	*GL*	*PL*
Barley	2.5–4.7	65–78	7–26	9–26
Maize/corn	5.1–6.0	88–96	3	5
Millet	1.7–11.0	75–94	1–15	1–14
Oats	4.5–10.3	66–80	6–10	12–26
Rice (brown)	0.9–3.1	78–87	4–12	8–10
Rye	3.5	63–71	10–12	18–25
Sorghum	3.6–6.0	77–86	2–6	11–17
Triticale	2.6–4.6	53–67	10–18	17–29
Wheat	2.1–3.8	60–72	12–22	14–26

TL = total lipids; NL = nonpolar lipids; GL = glycolipids; PL = phospholipids.

phosphatidylethanolamine (PE), and phosphatidylinositol (PI). Monoacylphosphoglycerides, or lysophospholipids (prefix L added to LP abbreviation, Table 1), are usually regarded as degradation products of PL. The GLs are quantitatively the major components of the glycolipids in whole cereal grains and starchy endosperm. The principal sugar in the GLs is galactose, and glucose is either a minor component or absent. The main galactosylglycerides are monogalactosyldiglyceride (MGDG) and digalactosyldiglyceride (DGDG). Small amounts of galactosylmonoglycerides (monogalactosylmonoglycerides (MGMG) and digalactosylmonoglycerides (DGMG) are also found in the endosperm of some mature cereal grains. Polar lipids are found in all membranes including the amyloplast membrane. Apart from these major acyl lipids, other lipids in cereals include sterols, and lipid-associated compounds such as carotenoids and tocopherols. Although carotenoids are very minor constituents in cereal grains, color contributed by carotenoids is an important factor in the use of cereal grains in food production, particularly in the use of durum wheat for pasta making.

The lipid content in cereals is influenced by the water content, the stage of maturity, and the variety of the grain crop. Lipids are also unevenly distributed in various parts of cereal grains (**Grain, Morphology of Internal Structure**). For example, in the wheat grain, the germ comprises only ~4% of the total grain, by weight, but it has the highest lipid content, and the highest proportion of polar lipids (Table 3), whereas the endosperm, the major fraction of wheat grain, has significantly lower lipid content than the other fractions. Lipids in flour (except whole meal) can be subdivided into nonstarch and starch lipids. The nonstarch lipids, which consist of all the endosperm lipids, excluding those inside starch granules, contain more GL than PL, whereas starch lipids are predominantly PL and almost exclusively lyso-PL in which LPC is the main lipid component. The distribution of lipid classes in other cereal grains is qualitatively similar to those in wheat. The germ is the richest source of lipids among all cereal grain

Table 3 Distribution and compositions of lipids in wheat grain fractions

Grains fraction	*Grain composition (%)*	*Lipid distribution (%)*	*Total lipids in each fraction (% w/w)*	*Lipid class (% w/w of TL)*		
				NL	*GL*	*PL*
Whole grain	100	100	2.1–3.8	60–72	12–22	14–26
Germ	4	30–35	25–35	79–85	0–3.5	14–17
Bran	4	2–5	2–4	72–80	6–10	13–18
Endosperm	92	60–70	1.5–2.5			
Nonstarch lipid				33–46	30–38	24–34
Starch lipid				4–6	1–5	90–95

TL = total lipids; NL = nonpolar lipids; GL = glycolipids; PL = phospholipids.

Table 4 Common FA compositions of total lipids in cereal grains

Lipid source	*Fatty acid (wt.%)*				
	Palmitic (16:0)	*Stearic (18:0)*	*Oleic (18:1)*	*Linoleic (18:2)*	*Linolenic (18:3)*
Wheat	17–24	1–2	8–21	55–60	3–5
Barley	21–24	1–2	9–14	56–59	4–7
Oats	7–26	1–4	22–48	31–52	1–4
Rye	12–19	1–2	12–16	57–65	3–12
Maize/corn	11–37	1–5	11–24	46–63	1–6
Brown rice	14–26	1–3	36–52	25–39	1–4
Sorghum	10–17	1–2	21–27	42–58	1–5
Triticale	16–20	1–2	8–14	57–60	4–6

fractions, more than one-third of the total lipid is in the germ. In particular, maize has a larger proportion of germ in the grain, 11–25%, by weight, with an exceptionally high lipid content, 39–47% by weight, containing mostly TAGs, with a small amount of PL and traces of GL. Maize germ is, therefore, more suited for edible oil production than any other cereal, after it has been separated from the starch endosperm (*see* **Oil from Rice and Maize**).

The FA composition of cereal lipids is generally similar for wheat, barley, triticale, maize, and sorghum (Table 4). All cereal grain lipids are rich in unsaturated FA. Palmitic acid (16:0) is a major saturated FA, and linoleic acid (18:2) is a major unsaturated FA for all cereals expect for brown rice. Rye lipids contain slightly higher levels of linolenic acid (18:3) than those of other cereals. Oat lipids are similar to those of brown rice; both are rich in oleic acid (18:1).

Oilseeds

Unlike the cereal grains, lipid (oil) is the main constituent of the oilseed crops. Oilseeds (*see* **Oilseeds, Overview**) such as canola/rapeseed, safflower, and sunflower are grown for their oil. On the other hand, oil is produced as by-product for other crops such as soybeans (*see* **Soybean**: Germplasm, Breeding, and Genetics; Agronomy; Grading and Marketing; Processing), which are grown primarily for their protein-rich content, and cotton (**Cottonseed**) grown for its fiber. Peanut (**Peanuts**), a leguminous oilseed, is not only used for edible oil production, but also for direct consumption as various human foods, being a good source of protein as well as oil. Another oilseed crop, linseed, produces oil that is not extensively used for food, but it is nevertheless an important industrial oil.

Table 5 Oil contents in oilseeds

Oilseeds	*Oil in dry seed (% w/w)*
Canola/rapeseed	30–50
Cottonseed	15–25
Linseed	35–45
Peanut	36–56
Safflower	12–47
Soybean	15–22
Sunflower	25–50

Lipid contents vary among the oilseed crops, shown as oil contents in Table 5, ranging from about 15% to 25% in soybean and cottonseed, to as high as 50% in sunflower, canola/rapeseed and 56% in peanut. It must be emphasized that both oil content and component FA proportions in an oilseed are subject to

Table 6 FA compositions of total lipids in oilseeds

Lipid source	*Fatty acid (% w/w)*					
	Palmitic (16:0)	*Stearic (18:0)*	*Oleic (18:1)*	*Linoleic (18:2)*	*Linolenic (18:3)*	*Others*
Canola	3–5	1–1.5	57–60	10–20	10–12	
Rapeseeds	1–3	0.7–1	12–14	11–22	8–10	20–50% erucic (22:1)
Cottonseed	18–25	1–2	17–38	45–55		1–3% myristic (14:0)
Linseed	5–7	3–4	18–20	15–17	52–60	
Linola			16	72	2	
Peanut	7–12	1–5	33–71	12–46		
Safflower	2–10	1–10	7–42	55–81		
Soybean	6–12	2–5	20–34	46–56	5–12	
Sunflower	5–7	2–6	15–35	60–73		

quite a wide variation. Such variations arise from genetic manipulation of seed varieties, from climatic factors and cultivation practices, and even from latitude of growth.

Lipids in oilseeds are predominantly TAG, ~90% or more of total lipids, and phospholipids being the main polar lipids. Other minor lipid constituents are FFA, sterols, hydrocarbons, etc. The FA composition of lipids is the main influence in terms of the "quality" and the uses of the oil. Cottonseed oil has high levels of saturated FAs among the oilseeds, 18–25% palmitic acid, and a small amount (1–3%) of myristic acid (Table 6). The main unsaturated FAs are linoleic acid (32–52%) followed by oleic acid (10–32%). The oil has a significant storage stability not only due to its lesser amount of unsaturated FAs content, but also due to the presence of enough tocopherols to reduce lipid peroxidation.

Among the common oilseeds, safflower, sunflower, and peanut oil contain high levels of unsaturated fatty acids. Sunflower oil is characterized by its high concentration of linoleic acid (60–70%) followed by oleic acid (15–35%). The high proportion of polyunsaturated FAs makes sunflower oil a popular source of essential FAs in the diet. Sunflower oil is next to safflower in having high levels of linoleic acid. The FA composition of safflower oil is similar to that of sunflower. The oil of commercial safflower cultivars contains 55–81% linoleic acid and 7–42% oleic acid as major FAs, followed by stearic (1–10%) and palmitic acid (2–10%) as minor FAs. In peanut oil, oleic and linoleic acids constitute 33–71% and 12–46% of the total FAs, respectively. A high proportion of unsaturated FAs in an edible oil, however, does decrease its storage stability and quality, due to oxidation reactions associated with the double bonds in unsaturated FAs.

Unlike other oilseeds, FA composition in rapeseed oil is unusual in that it contains substantial amounts of long-chain FAs, in particular, a significant amount of erucic acid (22:1) as ~20–50% of total lipids (Table 6). Major changes in the FA composition of rapeseed oils have arisen as a result of selective breeding for low levels of erucic acid. Because of some indications that erucic acid had anti-nutritional properties, varieties of rapeseed, called "canola," mainly grown in Australia and Canada, have been developed in which the level of erucic acid is essentially zero. Canola varieties are also characterized by markedly increased levels of oleic acid with smaller increases also in linoleic and linolenic acid content compared to those of the former rapeseed varieties due to the reduction of erucic acid content (Table 6). Canola oil has a FA composition similar to peanut with the exception of the lower palmitic and higher linolenic acid contents. Linolenic acid content has also been reduced in some canola varieties in favor of linoleic acid through breeding. A low-linolenic acid content canola variety has less than 2% linolenic acid, and resembles olive oil in terms of its monounsaturated FA content more than the high linolenic acid content oil variety.

Linseed oil is characterized by high levels of linolenic acid (52–60%), which undergoes autoxidation to give thin, cross-linked and tough films, making it unsuitable for edible purposes. It is, however, an important drying oil used to produce oil-based paints. Like canola/rapeseed, through plant breeding, a variety of linseed has been created in Australia, linola or solin, which gives an oil high in linoleic acid and contains less linolenic acid; it can be used for the production of margarine spread instead of sunflower oil. The "linola" oilseed, however, has not been commercialized in Australia, but is in commercial production in Canada.

Extraction and Quantification of Lipids

Accurate and precise analysis of lipids is important, not only for determining their nutritive values for human health benefit, but also for gaining the

knowledge of structural characteristics of lipids and understanding of their functional properties, which may allow development of tailor-made products that are designed for a particular function or application. Analysis of lipids involves several steps which unusually includes preparation of the sample, solvent extraction of lipids, removal of solvent, and separation of lipids into classes for qualitative or quantitative analysis. Sample preparation mainly involves particle-size reduction of plant tissues or seed materials using methods such as grinding. The purpose of this is to increase surface area and facilitate subsequent lipid extraction. In some cases, acid hydrolysis may be required to release lipids, which are covalently bound to proteins and carbohydrates.

The choice of organic solvents for lipid extraction largely depends on both the chemical nature of the sample and the type of lipids to be extracted, i.e., total lipids, starch lipids, polar or nonpolar lipids. Neutral lipids are hydrophobically bound and can be extracted readily by nonpolar solvents, whereas polar lipids, such as glycolipids and phospholipids, which are predominantly bound by electrostatic forces and hydrogen bonding, require polar solvents capable of breaking such bonds. Hexane and diethyl ether are preferred solvents for extracting nonpolar, neutral lipids such as triglycerides. Hexane is widely used for the industrial production of crude oil from oilseeds because of its low cost. However because of concerns about its toxicity, effort has been made to replace it with iso-octane, which is less toxic. However, cereal grains and milled flour contain relatively large amounts of glycolipids and phospholipids, and large amounts of cereal lipids (about half of the total lipids) are bound to polypeptides or polysaccharides. Therefore, more polar solvents such as chloroform, alcohol, or chloroform–methanol (2 : 1) mixture are needed for the extraction. In particular, water-saturated butanol is very effective in extracting starch lipids, as they are not readily dissociable from the starch by any other solvent system.

Removal of the solvent from lipid extracts is normally conducted under vacuum in a rotary evaporator at or near room temperature. Care must be taken to minimize lipid oxidation during sample preparation, solvent extraction, and storage of lipids. Cereal lipids characteristically contain large proportions of polyunsaturated FAs together with carotenoids and tocols, all of which are highly susceptible to autoxidation. The lipids are only slowly oxidized while the grain tissues are intact, but once the tissues have been disrupted, oxidation must be minimized by keeping lipids in solvents such as chloroform and under a nitrogen atmosphere, and by working at low temperatures if possible.

Lipid extracts are complex mixtures of individual classes of compounds and require further separation. Many chromatographic and spectroscopic techniques are in use to separate and quantify individual lipid components. The most commonly used techniques are thin-layer chromatography (TLC), high-performance liquid chromatography (HPLC), and gas chromatography (GC).

Thin Layer Chromatography

TLC provides separation of a wide variety of compounds with different polarities on a single plate. Silica is still the stationary phase material preferred. Small amounts of lipid material are spotted on a plate. The plate is then developed in a lid-covered glass chamber containing a mixed solvent system, which behaves like a gradient elution during travel on a plate. The separation of lipids is based on relative affinities of the components to the TLC adsorbant. When the solvent front is close to the top of the plate, the plate is removed from the chamber and residual solvent is evaporated under an inert atmosphere. The separated lipid spots can be visualized as brown spots (temporarily) by exposing to iodine vapor or under UV light after spraying with fluorescent agents, or dark spots (permanent) by spraying with sulfuric acid (10–50% in ethanol v/v) and subsequently charring above 160°C. The advantage of using a temporary nondestructive detection is that the lipid spots may be recovered from the silica gel for preparative or analytical proposes. Lipids, after separation on a silica plate, may also be quantitated by densitometric or fluorimetric scanning.

Lipids can be separated into various classes by TLC. As an example, Figure 2 shows the separation of wheat flour lipids extracted by chloroform from different flour mill streams, where more TAGs were detected in the later mill streams (lane 3) as more bran materials were being incorporated into flour. Straightforward unidimensional TLC is adequate for separation of nonpolar lipids and some polar lipids. In most cases, glycolipids overlap phospholipids in TLC systems that separate phospholipids. More complex GL or PL are preferentially separated by two-dimensional TLC, using a neutral/basic solvent such as in the first dimension, and an acidic solvent in the second dimension.

TLC offers a much higher sample throughput due to the possibility of performing separations simultaneously, and it can handle “not-so-clean” samples since the separation medium is used only once. TLC is a cost-effective, simple, and easy chromatographic technique.

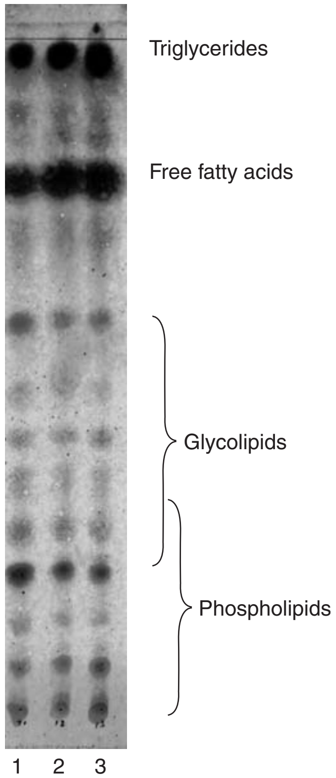

Figure 2 Separation of wheat flour lipids by TLC on a silica gel G plate (20 cm × 20 cm) developed in chloroform : methanol : water (90 : 20 : 2 v/v/v). Wheat flour was collected from different mill streams (1–3: early–late), where more TAGs were detected in the later mill streams as progressively more bran materials were being incorporated into flour.

High-Performance Liquid Chromatography

In principle, separations by HPLC are carried out by essentially the same separation principle as TLC. Using HPLC, it is easier to generate large numbers of "theoretical plates" (a measure of resolution efficiency); HPLC is simpler to automate than TLC. However, HPLC is much more expensive than TLC in terms of both equipment and running costs. HPLC separation occurs in a stainless steel column packed with a very uniform, finely divided, microspherical adsorbant material of controlled porosity and degree of hydration. A high-pressure pump ensures adequate and constant flow of solvent, the "mobile phase," through the column, and a flow-through detector continuously monitors the column eluate. Adsorption chromatography with columns of silica gel is commonly used for the separation of lipids. Elution of the column may be carried out either with a solvent mixture of constant composition or by gradient elution, in which the solvent composition is varied linearly or in a stepwise fashion with both binary and ternary solvent systems. The choice of the elution

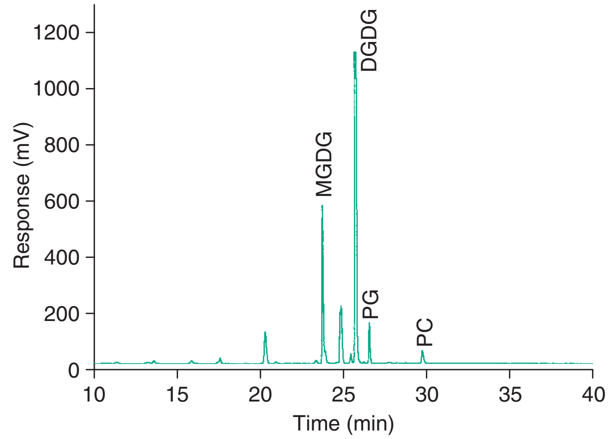

Figure 3 HPLC analysis of wheat flour polar lipids extracted by chloroform. Separation was carried out on a PVA-Sil threaded guard column (23 × 4.0 mm i.d.) with gradient elution at 0.5 ml min^{-1} and detected by a ELSD. Four steps of gradient were used for the separation – 0–10 min: 100% eluent A (2,2,4-trimethylpentane); 10–20 min: 90% eluent A + 10% eluent B (tert-butylmethylether); 20–35 min: 100% eluent B; and 35–40 min: 100% eluent C (methanol/n-ethylmorpholine/glacial acetic acid (500 : 4.2 : 1.5 v/v)). For abbreviation of lipids see Table 1.

systems is sometimes restricted by the use of the detection system. For example, a solvent mixture of constant composition with low UV absorbance may be essential for a UV detector. Although gradient solvent systems can be used with an evaporative light-scattering detector (ELSD), the choice of solvents is constrained by the need for sufficient volatility for evaporation in the detector under conditions that do not cause evaporation of the solute. Complicated programs (up to eight steps) are sometimes required to achieve the desired separations. However, ELSD has presently become the detection method used most often in the separation of lipids by HPLC. HPLC for analysis of all simple lipid classes in one chromatographic run, , has not yet been used widely, probably because TAG (major components in all cereal grains and oilseeds) dominate the system. HPLC methods have been devised more for specific analysis of individual components. The use of HPLC for the separation of complex lipids has increased. Separation of glycolipids MGDG and DGDG, along with several phospholipids from wheat flour lipid extracts at analytical scale (Figure 3), as well as preparative scale, has been achieved.

Gas chromatography

GC is the most useful tool for the analysis of the FA composition in lipids. Derivatization of FAs is required to increase their volatility. Fatty acid methyl esters (FAMEs) may be prepared by different transmethylation techniques and then separated on

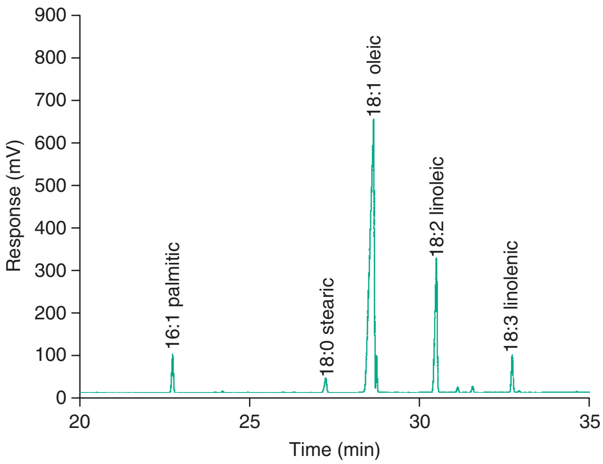

Figure 4 GC analysis of a canola oil. FAs methyl esters separated using a capillary GC column (SP2560, Supelco) and detected by an FID at 240°C.

GC columns and detected by a flame ionization detector (FID). The gas phase for GC is usually nitrogen or helium for packed columns and helium or hydrogen for capillary columns. Since the principal FAMEs in cereal lipids are 16:0, 16:1, 18:0, 18:1, 18:2, and 18:3, heptadecanoic acid (17:0) can be used as an internal standard. Identification and quantification of individual FAs can be achieved by comparing and calibrating with relatively cheap FAME standards. Figure 4 shows a typical GC profile of FA compositions in canola oil. FA compositions in lipid classes can also be obtained by GC analysis of lipids in each class separated or prepared by TLC or other column chromatography techniques.

Lastly, mass spectrometric detection is being used increasingly for the detection and analysis of complex lipids. The technique can be used with direct inlet injection or linked to HPLC, or GC systems where the mass spectrometer serves both to detect lipids and to obtain information on their molecular structure.

The Role of Lipids in Cereal Technology

Apart from being used directly as a source of human food and animal feed, a large proportion of cereal grains is milled to flour, which is then used for producing various food products. Wheat has been the predominant cereal grain used for baked goods, largely due to its ability to form a dough when flour is mixed with water. Rye ranks next in importance while other cereals assume a role in specialized products and in the preparation of composite flours.

The rheological properties of doughs made from wheat flour are principally determined by the gluten protein (**Gluten and Modified Gluten**), and lipids (naturally occurred in cereal grain, excluding added fat) appear to make little contribution. When protein is removed from a flour, dough and bread-making properties are lost. In contrast, good dough properties and bread-making capacity are retained after removal of the nonstarch lipids. However, flour lipids do affect the loaf volume and crumb texture of bread. Fractions of polar and nonpolar lipids have opposite effects on baking performance.

Incremental addition of the extracted lipid to a defatted flour produces an unusual effect on the loaf volume and texture in a rapid baking test in which exogenous lipid is omitted. Loaf volume decreases to a minimum at a lipid content intermediate between that of the defatted and untreated flour, thereafter increases. At high lipid contents (above the inherent lipid content of the flour), the loaf volume–lipid curve tends to plateau. The changes in volume are paralleled by changes in crumb grain which, at first, also deteriorate and then improve. Fractions of polar and nonpolar lipid affect loaf volume and crumb grain in opposite ways. The polar lipid fraction has generally beneficial effects, whereas the nonpolar fraction has deleterious effects. Thus, if the ratio of polar to nonpolar lipid is increased, the minimum of the loaf volume–lipid content curve is shifted to lower lipid contents. If the percentage of polar to nonpolar lipid in a flour is varied from 0 to 100 at a constant lipid level, test-bake loaf volume increases approximately in a linear manner. Addition of different lipids to test their effects on dough has shown that the unsaturated FAs such as linoleic acid are the components that mainly contribute to the deleterious effects of the nonpolar fraction. Higher loaf volume and better crumb texture in bread is favored by a high ratio of polar/nonpolar lipid and a high content of flour lipid. However, the variation in loaf volume that can be attributed to lipid is relatively small, and by far the greatest variation is imposed by the effect of gluten protein quality.

The effects of lipids have also been studied for Arabic bread, steamed bread, cakes, and biscuits. Despite differences in processing, the general features with respect to lipids have much in common. It is the crumb texture which is influenced most and, like bread, differences in lipids have not been found to account for major variations in quality. The role of the (polar) lipid appears to act as a complex mixture of components with surface activities in stabilizing or destabilizing the gas bubble structure during expansion of the loaf and thus the final texture.

In addition to their effects in influencing volume and texture of baked products, lipids also play a role in staling mechanisms. Generally, the presence of lipid reduces bread staling and enhances shelf life.

This is largely due to the interaction between lipids and starch. When monoacyl lipid monomers are present to form the lipid–starch complex, an insoluble amylose-lipid film is likely to be formed on the surface of the starch granules. Such a film is capable of acting as a barrier against water transport involved in the staling process.

The contribution of the lipid component to flour quality should not be ignored when considering parameters to be used as a basis for selection in plant breeding programs even though protein composition appears to be the major factor that determines flour quality. The "quality factors" in flour lipid, as presently known, are a high nonstarch lipid content, a high ratio of polar to nonpolar lipid, and a low free-fatty-acid content.

Oils and Nutrition

Lipids are the richest source of energy on a weight basis. They also play a significant role as barriers, such as for skin and in stabilizing biological membranes. Appropriate intake of lipids is essential for health maintenance. However, a high consumption of fat, especially saturated FAs, may be connected with several chronic diseases, such as heart disease and obesity. Of the lipid components of a normal diet, the most important FAs are linoleic (n-6 PUFA) and α-linolenic (n-3 PUFA) acids, the two primary essential FAs. They play a role in stabilizing biological membranes by creating physical properties that are optimal for the transport of substances across the membrane and for the biochemical reactions occurring in the membrane. Through metabolism, they are converted into a whole range of oxygenated compounds, which exert a range of profound physiological activities involving lowering plasma cholesterol, aggregating red blood cells, and smoothing muscle performance, all attributes that are required for good health. Since the human body is unable to synthesize them, they must be obtained from dietary sources.

The important source of the essential FAs is oilseeds. Although cereal grains contain high amounts of linoleic acid, due to the generally low total lipid content of the grain, it is unlikely to have much contribution to the essential FAs intake in the human diet, except when the lipids are extracted from the lipid-rich germ and produced as oil, such as maize germ oil (**Oil from Rice and Maize**). Oils extracted from oilseeds, however, have a sufficient influence in total fat intake of the human diet since they are used directly for frying foods, as cooking ingredients and as spreads.

LUPIN

Contents

Overview

D S Petterson, Department of Agriculture, Nedlands, WA, Australia

Definition and Origins of Lupins

The seed or grains of domesticated *Lupinus* species are generically called lupins. The same term is used widely in the community in referring to wild and domesticated plants and seed/grain of all *Lupinus* species. The genus *Lupinus* belongs to the Fabaceae, a family of legumes. There are 12 lupin species, all large-seeded, native to Europe and the Mediterranean regions. Three of these are now fully domesticated. *Lupinus albus*, the European white lupin or Albus lupin has a white flower. Wild types of *L. angustifolius*, the narrow-leafed lupin, have a blue flower: however modern cultivars bred for low alkaloid content in Australia have a white flower and are known widely as the Australian sweet lupin (ASL). *Lupinus luteus*, the yellow lupin (YL), has a yellow flower. Their grain is widely used in the animal feeds industry and to a lesser extent as a food (or food ingredient). There are ~100 lupin species native to the Americas. They are mostly small-seeded and only *L. mutabilis*, the pearl or Andean lupin, has been used as a food source. Worldwide, several species are being domesticated for possible use in agriculture (*see* **Lupin**: Breeding). The main value of lupin crops to farmers are their replenishment of soil nitrogen, providing a disease-break for cereals in crop rotation systems, and a marketable grain. Lupins tend to grow relatively better on poorer soils than most other crop species (*see* **Lupin**: Agronomy).

Lupins are also well known for their spectacular flowers. The Russel lupin, a hybrid derived from *L. polyphyllus*, is widely used as an ornamental flower, particularly in Europe. Parts of the southern highlands on New Zealand are a blaze of color from the alpine lupin, a variant of the Russel lupin, in springtime and early summer. The (bluebonnet) flower of *L. texensis* is the floral emblem of Texas.

It is widely accepted that *Lupinus* evolved from the tropical and subtropical Sophorea, a primitive tribe of the subfamily Papilionoideae (pea flowering plants), 40 million years ago. Nowadays, wild lupin species cover almost all climatic zones; sub-Arctic Alaska and Iceland, Mediterranean and semidesert regions, the highlands of East Africa, Mexico and the Andes, and the subtropical lowlands of the Eastern Americas.

Grain Morphology and Composition

Lupins have a typical dicotyledon structure (*see* **Grain, Morphology of Internal Structure**). Their thick seedcoat (hull or testa) comprises ~30% of the seed weight for *L. luteus*, 25% for *L. angustifolius*, 15% for *L. albus*, and 12% for *L. mutabilis*. This is considerably higher than for most domesticated grain species. Within the cotyledons (kernels), energy is mostly stored in the form of thickened cell-wall material (~25% of the cotyledons) and oil bodies (~6–14%). There is virtually no starch in any of the lupin species. This is in marked contrast to crops such as field peas and chickpeas, which can have 50–70% of the cotyledon weight as starch and have low protein and oil content, and the soybean with 15–20% oil, some starch and a high protein content. Their crude protein content ranges from ~28% to 42%. Proximate analyses for whole grain of the major domesticated species, and the Andean lupin, are shown in Table 1. There are some wild and partly domesticated *Lupinus* lines containing up to 45% crude protein and up to 21% oil, others have as little as 20% crude protein and 3% oil.

The thick seedcoat, which is mostly cellulose and hemicellulose, of *Lupinus* species means that it is important to also consider the composition and nutritional value of their cotyledons: these data are in Table 2.

Valine	1.4	1.2	1.3	1.7

[a] Data are averaged from values obtained worldwide.

The major lupin proteins are a group of globulins, called conglutins. The three major ones are conglutin α (which sediments at ~11–12S and is analogous to legumin of peas and glycinin of soybeans), conglutin β (which sediments at ~7S and is analogous to vicilin of peas and conglycinins α and β of soybeans), and conglutin γ (a sulfur-rich protein which sediments at ~2S and is analogous to conglycinin of soybeans). They comprise ~85% of the total protein and have similar size and physical properties to the storage proteins of other grain legume species. The remaining 15% of proteins are albumins, which are soluble at pH 5 and vary in size from ~6000 to 117 000 Da. There is evidence for the 2S globulin actually being an albumin: depending on the species, this fraction consists of 4 (*L. luteus*), 5 (*L. albus*), or 6 (*L. angustifolius*) proteins. For more details on lupin and other legume proteins, *see* **Cereals**: Protein Chemistry.

Typical amino acid profiles for the domesticated lupin species, compared to FAO standards for infants and others, are shown in Table 3. The deficiencies in lysine and methionine are common to most grain legumes.

The seed hulls and cotyledons contain different types of carbohydrate. Lupin hulls are predominantly composed of structural polysaccharides: cellulose, hemicelluloses, and pectins. The main carbohydrate reserves of the cotyledons are the nonstructural polysaccharides of the cell walls, with the main components being galactose, arabinose, and uronic acid. These complex compounds are referred to as nonstarch polysaccharides (NSP). Their structure, based on a rhamnogalacturonans backbone, is not yet fully defined. The water-soluble portion, ~5% of the seed, is considered to have an antinutritional effect due to its viscous nature and effect on intestinal transit time.

The insoluble NSP, ~30% of the seed, has a minimal effect on nutrient utilization by monogastric species. An important attribute of insoluble NSP is their ability to hold large quantities of water, about eightfold by weight for lupins, and maintain normal gut motility. The profiles for various species are shown in Table 4. The oil content of lupins varies from ~15% in the pearl lupin down to 4% in the YL. There are differences in individual fatty acid profiles, they are typically high in oleic and/or linoleic acids and contain a total of ~75% unsaturated fatty acids (cf. ~85% in olive oil). The oil is heat-stable and has a high antioxidant capacity.

Variation in the content of major essential minerals in lupins, up to ~30% of the mean, is typical of legume species, probably reflecting both genotype and environmental factors (Table 5). The essential trace mineral content of lupin species is influenced by genotype but also tends to reflect the soil types on which they are grown. For example, the selenium content of lupin seed grown in Western Australia varies according to species and rainfall zone. Where the species were grown together, the selenium content of *L. albus* > *L. luteus* > *L. angustifolius*. In all cases, the higher the rainfall, the lower the selenium content. Similar variations apply to the content of copper, cobalt, and zinc in lupins. The accumulation of manganese by *L. albus* is well documented with most of the low values coming from crops grown on sandy soils and high values coming from crops grown on heavy red clays. In contrast, the manganese content of *L. angustifolius* is low, from 9% to 30% the amount in *L. albus* grown at the same site (Table 5).

A survey of the cadmium and lead content of *L. angustifolius* (178 samples) and *L. albus* (12 samples) grown in Australia found no samples exceeded the Codex Alimentarius limits of 0.1 and 2.0 mg per kg, respectively. There can be some accumulation of cadmium by *L. luteus*, which may be a consequence of the different root architecture in this species and the soils in which it is grown.

Legume grains contain a range of compounds, traditionally known as antinutritional factors (ANF) or antinutrients, with apparent untoward effects on species ingesting them. These are also known as bioactive compounds. These compounds had a protective role in evolution by protecting against predators and may have other important functional roles. Plant breeders have mostly reduced their content to a point of balance between lowering the content of ANF, to enhance the nutritional value of the grain, and retaining the defensive or, otherwise, functional role. While some ANF have a negative effect on feed utilization by farmed livestock, they can also have beneficial effects in humans, such as preventing the development of some forms of cancer and of osteoporosis. A summary of data for the ANF content of lupins is shown in Table 6.

The content of proteinaceous ANF in domesticated lupin species is very low. Typically, trypsin inhibitor activity is <0.3 mg per kg, and chymotrypsin inhibitor activity <0.6 mg per kg. Lectin activity is virtually nonexistent in all lupin species. So, unlike most legume grains, lupins do not need to be heated to denature the proteinaceous ANF and make them safe for consumption by humans or animals.

Phytate (inositol hexaphosphate and lower substituted homologues and their salts) contributes about one-half of the total phosphorus content in lupins. This is rapidly mobilized upon germination. Phytate can form insoluble complexes with divalent cations, particularly Ca^{2+} and Zn^{2+}, thus making them less

Table 4 Nonstarch polysaccharide components for major lupin species (g per kg in grain)[a]

	L. albus (Albus lupin, white lupin)	*L. angustifolius (Australian sweet lupin, narrow leaf lupin)*	*L. luteus (yellow lupin)*

Mineral content (μg per kg)			
Cobalt	10–430	10–260	na
Selenium	20–360	18–240	na

na = not available.

available for absorption and utilization. The net effect of phytate in the diet depends on the overall composition of the food particularly the amount and types of protein content and the total mineral content. Human studies have shown similar rates of absorption of phosphorus from lupin-based foods and comparable soy products. Germination lowers the phytate content by ~60% and fermentation by ~80%.

Tannins are compounds of plant origin with molecular weights ranging from 500 to 2000 Da, and with one to two phenolic hydroxyl groups per 100 Da. This enables them to form cross-linkages between proteins and other macromolecules. There are two subgroups of tannins. Hydrolysable tannins typically have a central glucose core with the hydroxyl groups being wholly or partly esterified with gallic acid or hexahydrodiphenic acid. Condensed, nonhydrolysable tannins are higher oligomers of flavan-3-ols with varying degrees of substitution. Their astringent taste and ability to precipitate proteins, resulting especially in the inactivation of gut enzymes, give the tannins their antinutritional role. In lupins, as with other grain legumes, the tannins are concentrated in the seedcoats (hulls) and the simple act of de-hulling will minimize any adverse effects. The concentration of condensed tannins, those most responsible for protein binding, is so low in lupins that it is unlikely to affect human or animal nutrition.

Saponins are plant glycosides in which the non-sugar moiety is a steroid or a triterpenoid compound. Their bitter taste acts as a feed deterrent, and they have a secondary antinutritional effect by increasing the permeability of small intestinal mucosa cells. This causes a loss of essential electrochemical concentration gradients, facilitating the uptake of materials to which the gut would not normally be permeable. Only traces of saponins are present in *L. albus*, while concentrations in *L. angustifolius* and, *L. luteus* range from 55 to 730 mg per kg. Saponins are generally harmless to humans: some are claimed to be beneficial in lowering blood cholesterol levels and protecting against coronary heart disease. The concentrations in lupins are lower than in many other legume species.

Table 6 Antinutritional factors in the major lupin species[a]

Botanical name	*L. albus*	*L. angustifolius*	*L. luteus*
Total alkaloids (mg per kg)	<200	<200	200–500
Oligosaccharides (%)	7.5	5.2	12.3
Saponins (mg per kg)	<1	570	55
Condensed tannins (%)	0.01	<0.01	0.02
Lectins (activity[b])	trace	trace	trace
Trypsin inhibitors (mg per g)	0.13	0.14	0.29
Phytate (%)	0.79	0.58	0.96

[a] Data are averaged across worldwide figures.
[b] Lectin activity is usually measured as units of agglutinating activity against red-cell preparations from blood of various mammalian species. Several authors argue that there is no significant activity in *Lupinus* species, some have detected activity against specially sensitised cells or against species not considered significant for human concern.

Lupin oligosaccharides are higher α-galactosides of sucrose. Raffinose has one galactose moiety linked to sucrose through an α 1,4 bond, while stachyose has two, verbascose three and ajugose four. These compounds cannot be metabolized by humans and other nonruminant species, and they undergo bacterial fermentation in the colon to produce carbon dioxide, methane and hydrogen. This causes abdominal discomfort and cramps and leads to flatulence, which seems to be a major reason for the low interest in consuming grain legumes in many societies. The oligosaccharides are a rich source of nutrients for bifidobacteria in the colon. This can have a beneficial effect, as the bifidobacteria counter the activity of putrefying bacteria and reduce their production of harmful, and possibly carcinogenic, fermentation products. One further source of confusion about the significance of oligosaccharides is the inclusion by some authors of sucrose in their total for oligosaccharides. This is nutritionally confusing as sucrose can be absorbed from the stomach and upper digestive tract of humans and nonruminant animals.

Isoflavones have generally been regarded as ANF because of their negative effects on fertility in ruminants grazing pasture medics and subterranean clovers. However, they are now recognized as preventative agents against some forms of cancer and osteoporosis in women. Isoflavones are present in green-leaf material and in the hypocotyls of germinating seeds (sprouts). There is conflicting evidence as to their presence in mature grain.

The lupin alkaloids are usually bicyclic, tricyclic, or tetracyclic derivatives of quinolizidine (Figure 1). The individual alkaloids and their concentrations vary widely between, and sometimes within, species (Table 7). Grain of modern domesticated lupin cultivars typically contains less than 200 mg per kg alkaloids. In contrast, grain from "bitter" wild types that still exist in many countries may contain from 5000 to 40 000 mg per kg alkaloids. There have been human deaths associated with the consumption of grain from bitter wild types of lupin. One would need to eat ~10 kg of the modern varieties of lupin

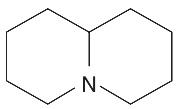

Figure 1 Structure of quinolizidine.

Table 7 Quinolizidine alkaloids in the major lupin species (% in alkaloid fraction)[a]

	L. albus	*L. angustifolius*	*L. luteus*	*L. mutabilis*
Albine	15			
Lupanine	70	70		70
Multiflorine	3			
13-Hydroxylupanine	8	12		2
4-Hydroxylupanine	1			7
Angustifoline		10		<1
Lupinine			60	
Sparteine			30	20

[a] Data are for modern cultivars or developing lines of these species. Up to 10% gramine, an indole alkaloid, is present in *L. luteus*.

grain in a very short time to absorb sufficient alkaloids to be at risk. The quinolizidine alkaloids have a short half-life in humans and are excreted largely unchanged in the urine of $>90\%$ of humans. Traces of gramine, an indole alkaloid, occur in some lines of *L. luteus* but the significance of these levels is not known.

The only mycotoxin associated with lupins to date is the family of phomopsins, a group of linear hexapeptides with an antimicrotubule effect which is most pronounced in the liver and kidney. They are capable of disrupting mitosis and of reducing the activity of motile cells and organisms, rendering their host prone to secondary infections. There is no relationship between lupinosis and lupin-alkaloid poisoning that can occur when sheep graze bitter lupins and their stubble, or graze the perennial lupins of North America. Grains that contain phomopsins are smaller and less dense than normal-colored, nontoxin containing grain and can be easily removed from the rest of the harvested grain by grading, using screens, gravity tables, and aspirators. A rapid enzyme-linked immuno-sorbent assay for the phomopsins is readily available to the food industry. The most recent cultivars of *L. angustifolius* are resistant to invasion by the responsible fungus (*Diaporthe toxica*), so that the risk of phomopsins ingestion is now extremely low, and likely to be even less in the future.

Grain Processing

De-Hulling

The simplest processing of lupin grain is repetitive abrasion of the testa in a ripple flow mill, tangentially abrasive de-hulling device, or similar device. (The thickness and hardness of the testa make it harder to de-hull lupins than most grains.) Alternatively, the grain may be conditioned by the addition of water, to swell the grain, followed by a mild heat treatment to help break the bonding between testa and cotyledons. It is then possible to de-hull using the same roller mills as used for milling wheat and other cereals. The major components are separated by air aspiration and grading across gravity tables. The germ fraction usually separates with the hulls, and is mostly lost.

The main reason for de-hulling is that the cotyledons are much more nutritious than whole grain for nonruminant animals such as pigs, poultry, and fish. It is then possible to mill the cotyledons to make flour, or to separate it into protein-rich and fiber-rich fractions for the feed, human food, and cosmetic industries.

Milling

Hammer milling of whole grain to make a coarse meal is common in the animal feed industry, simply to make the constituents more available to ruminant animals by increasing the surface area of material for digestion, and in some cases where it may be uneconomic to de-hull for nonruminant feeds. Hammer cutting and roller milling of the splits are used to make a meal or fine flour for nonruminant feeds. The particle size range can be from 10 to 800 μm, which is far greater than for cereal, pea, and soy flours.

Fractionation

Several reports in the scientific literature and patents describe the separation of protein, fiber, and oil fractions from cotyledons. Some processes cater for recovery of alkaloids, for use as biological agents against insect pests and some microorganisms, and low-molecular-weight carbohydrates for use in the chemicals industry. These mostly involve wet grinding of the cotyledons and separation of fractions according to solubility at different pH or in different solvents. There may be an initial dry milling and separation of particles by air classification.

Extrusion

Extrusion (*see* **Extrusion Technologies**) can improve the quality of lupin-based formulated feeds. There is no expansion of the pellets as with starch-enriched feeds, but there are improvements in feed digestibility, which makes the process cost-effective.

Food Uses

Traditional Uses

Lupins have been used as a food for as much as 6000 years in the Andean highlands, and over 3000 years around the Mediterranean. The pearl lupin of the Andean Highlands of South America known locally as "tarwi" or "choco," was extensively cultivated, and consumers would soak the seed in running water to remove most of the bitter alkaloids before toasting or boiling and drying to make "kirku." Andean people have long recognized the benefits of consuming lupins, associating their use with religious festivals. In South America, the traditional use of tarwi as staple food continues in many Andean communities. Around the Mediterranean lupini beans, large-seeded bitter grain of *L. albus*, have been extensively used as a snack food, and as a bean substitute in times of drought. They are still commonly used as a bar snack. The beans (grains) are substantially debittered before being pickled and bottled or canned for use as a snack food. In the Middle East, the grain of *L. albus* is used to make snack foods, most commonly at the time of Ramadan (several thousand tons are imported from Australia each year for this). They are usually boiled whole and spiced, with the testa being removed before eating. Another use is to make a paste similar to the traditional "falafel" from faba beans.

Bean/Sprout

Immature seeds do not yet contain any alkaloids and have a similar taste and nutritional value to immature (green) peas. They can be used as an alternative to soybeans to make "edamame." Lupins can be germinated to make a sprout suitable for vegetable or salad use. Germination lowers the content of alkaloids, phytate, and oligosaccharides on a dry-weight basis, but also the overall content of the protein fraction. The lupin sprout compares favorably with soy and mung sprouts for taste and texture, although it has a slight beany and bitter aftertaste. Unlike most species, there is no vitamin C production on germination. There is, however, considerable production of the isoflavones, genistein, and daidzein.

Whole seeds may be deep-fried or made into spreads similar in nature to "hummus" (traditionally made from chickpeas) and falafel (traditionally made from faba beans) and used with salads or breads.

Fermented Foods

"Tempeh" is a traditional Indonesian food, made by two successive fermentations using soybeans as substrate (*see* **Fermentation**: Foods and Nonalcoholic Beverages. **Soybean**: Soymilk, Tofu, and Okara). A bacterial fermentation during the soaking of cooked de-hulled soybeans is followed by a solid-state fermentation of the bean mass by the mould *Rhizopus oligosporus*. Tempeh has been successfully made from *L. albus*, *L. angustifolius*, and blends of both with soybeans. Indonesian consumers like the taste of lupin-based tempeh but frequently comment that the texture is too firm. The production of second-generation products, such as burgers and patties, from lupin-based tempeh seems to overcome this objection.

"Miso" is a fermented paste made from soybeans, usually mixed with rice (*see* **Soybean**: Soy-Based Fermented Foods). A traditional process involves preparing a rice "koji" by fermenting cooked rice with a culture of *Aspergillus oryzae* ("tane-koji"), and then adding cooked soybeans and salt to the koji. Lupins have been used experimentally to make miso of comparable quality to soy miso. "Natto," another Japanese fermented food, can also be made from lupin grain.

"Shoyu" is the traditional soy sauce of Japan (*see* **Soybean**: Soy-Based Fermented Foods). Some Japanese people now use lupin shoyu as an alternative. Lupins can be used to make sauces similar in flavor and texture to the traditional soy sauces of China, Korea, and Indonesia.

Several thousand tons of Australian sweet lupins have been used commercially in Indonesia for tempeh production, and small commercial batches of lupin-based miso have been sold in Japan.

Flour Additive

Lupin kernel flour can be mixed in with wheat or wholemeal flours to make bread more nutritious, by giving a better balance of essential amino acids. Legume grains contain relatively more lysine and less methionine than cereal grains; so adding $\sim$10% lupin flour to wheat flours will give a product with similar properties to the full-wheat product, but with an improvement in amino acid score from under 40% to over 70% relative to egg albumin. Loaf volume is compromised with increasing lupin content but fortifying with gluten or using harder wheat in the blend can overcome this. In practice, the limit of inclusion is $\sim$10%. There is an increase in water-holding

capacity. The texture, flavor, and golden color of the lupin-wheat flour is appealing to many consumers. In Australia, some bread manufacturers use lupin-hull flour to provide "bulk" in high fiber breads. Ultra fine kernel flour has an attractive yellow color, good dispersion in aqueous systems, and good emulsifying properties. Albus lupin flour can be added into wheat flour to make the traditional Chilean breads "hallula" and "marraqueta." Up to 10% micronized flour from *L. albus* cotyledons could be included in breads, biscuits, and cakes, enhancing protein quality, color, and taste. The added lupin flour retards staling, probably by increased water retention and better emulsification properties. Studies have shown a high acceptability of pasta enriched with *L. angustifolius* kernel flour, and up to 15% substitution of *L. albus* flour for semolina or durum flours enhanced the protein quality and appearance of spaghetti noodles without affecting sensory qualities. Flour from *L. albus* has been blended with noodle wheat flour to make unsalted white noodles with an improved protein and dietary fiber contents, and color and texture. Up to 50% lupin flour can be incorporated into a range of cakes and biscuits.

There are several suppliers of lupin flour, and other products in Europe, but there are no available data on sales.

Lupin Kernel Fiber

The purified cell-wall fraction from lupin kernels is virtually colorless, odorless, and tasteless and can hold up to 8 times its own weight of water. The fiber has cholesterol-lowering properties, and acts as a fecal-bulking agent thus reducing stool transit time and benefiting bowel health. It also enhances satiety, probably due to its high water-holding capacity, and has potential as an antiobesity agent. The soluble fiber fraction can function as a fat replacer. The fiber can be used to supplement breads, pastas, biscuits, mousses, and jellies.

Protein Fractions

Lupin kernel proteins have some valuable functional properties, combining good emulsifying, foaming, water- and oil-holding properties but with less thermal stability than soy proteins. Nevertheless, lupin-protein concentrates and isolates are used as meat extenders, and refined fractions used to enhance the foaming properties of dairy desserts and other foods.

Vegetable Milk Products

A lupin-based milk was used in the Chilean program for children's nutrition for several years, and is still used by households in some parts of the country.

In making "tofu" (*see* **Soybean**: Soymilk, Tofu, and Okara), it is possible to incorporate up to 30% lupin (*L. angustifolius*) milk with soymilk before the coagulation stage and produce an acceptable product, with the advantage of a lower unit cost of production. Higher levels of incorporation are not possible because the lupin proteins lack the necessary tertiary structures to produce a good curd. Sensory evaluations showed that tofu from a 30/70 lupin/soy blend was equally acceptable as a tofu made from soymilk.

Fermentation of lupin milk produces a yogurt-like product of stable texture and with no beany flavor. It is comparable to the yogurts made from soymilks.

Malted lupins could be used as a health-drink base. The presence of the beneficial isoflavones – genistein and daidzein – in the hypocotyls of developing lupin sprouts is well-reported. Lupin tea, made in the same way as pearl barley tea, has been developed in Japan.

Allergenicity of Lupins

There are some reports of lupin allergenicity in the medical and scientific literature. Nearly all of the affected subjects had a history of reactions to other protein foods (e.g., peanuts, soybeans, shellfish). The evidence to date suggests that lupin proteins have a lower allergenicity than most other protein foods.

Feed Uses

Ruminants

Almost all of the testa can be fermented in the rumen so there is no need to de-hull lupins for ruminant feeds. The whole grain is highly fermentable with a minimal risk of acidosis. It is best to crack the grain open as a minimum action, to increase access for the rumen flora, but any grinding should not be too fine because there can be a loss of material to the hind gut where it is used less efficiently. A significant amount of protein degradation occurs in the rumen, but some protection from this is possible by treating the grain with formaldehyde before feeding. Other methods include flame-roasting the grain, steaming, and rolling the grain into flakes, and coarsely grinding the grain and then extruding the meal (*see* **Extrusion Technologies**).

Lupins are a valuable component of diets of feedlot cattle (up to 40% of the diet), and milking cows can readily consume large amounts of (cracked) grain whilst in the milking sheds. Rangeland farmers often supplement their grazing sheep with 50–250 g grain per head per day in dry periods when pastures are low. There is ample evidence for an enhancement of reproductive performance of both

rams and ewes when their diets are supplemented with lupin grain prior to mating. No specific factor has been attributed to this.

Several hundred thousand tons of grain are retained on-farm in Australia each year for grazing supplements for sheep. The greatest consumption of traded lupin grain is by cattle, either in feedlots or under intensive housing when fed formulated diets containing lupin grain.

Nonruminant Animals

The testa is virtually worthless to all nonruminant species. It is removed whenever economical to do so. Otherwise, it simply supplies some bulk nonfermentable fiber. Processed lupin kernel meal is frequently used in commercial feeds for pigs, poultry, and aquatic species. The actual inclusion levels will depend on price and availability of the meal and alternative ingredients as well as any constraints imposed by any individual ingredient. The meal is low in lysine and methionine relative to most animal needs, but this is not a significant problem. First, this deficiency is reflected in the price of the ingredient; secondly, deficiencies of one ingredient in the formulation will be at least partly offset by other ingredients; and thirdly, crystalline amino acids are readily available to the feeds industry.

Pigs The digestible energy (DE) value of whole lupin grain for pigs is $\sim$14–15 MJ kg^{-1}; however there is a lot of hindgut fermentation and the net energy value is $\sim$10.5 MJ kg^{-1}. Nevertheless, lupins are widely used in the pig industry. Recommended inclusion levels of ASL vary from 100 to 350 g per kg depending on the age and physiological status of the animal. Yellow lupins have a similar energy value and are also widely used. Albus lupins are not used because they contain an inappetence factor for pigs. This reduces feed intake, slows growth, and makes it uneconomic to use such a diet.

The addition of industrial carbohydrase enzymes to lupin-based pig diets can improve their net energy value.

Pigs rank second to cattle in the overall consumption of lupin grain, almost entirely as a component of formulated feeds.

Poultry The apparent metabolizable energy (AME) content of both ASL and YL grain is $\sim$8.6 MJ kg^{-1}. It is not practical to use more than 100 g per kg feed because of the high water-holding capacity of the undigested carbohydrates, which can cause wet droppings. For layer birds, it is possible to include up to 300 g per kg in the diets, as the wet droppings are less of a problem. Albus lupins can be readily included in poultry diets. There is some benefit from adding carbohydrase enzymes to poultry diets. The oligosaccharides in lupin meals seem to have a beneficial effect on osmotic stability of the gut enhancing nutrient absorption.

Poultry ranks third as consumer of lupins in formulated feeds.

Finfish and crustaceans Lupins can be used in both high-nutrient density (HND; high protein and oil content) and low-nutrient density (LND; low protein and oil content) diets for finfish. When included in HND diets fed to rainbow trout (*Oncorhynchus mykiss*), the DE value of lupin kernel meals ranges from 12.8 MJ kg^{-1} for *L. angustifolius*, to 14.8 MJ kg^{-1} for *L. albus*. Protein digestibility of all lupin varieties when fed to fish is high, typically greater than 95%. The low essential amino acid content is less of a problem for finfish fed HND diets than for pigs and poultry because of the high level of protein required in the diets restricting the practical inclusion levels of the meal and also that so much of the dietary protein is metabolized as an energy source. Good acceptance and palatability of HND diets containing *L. angustifolius, L. albus*, and *L. luteus* has been reported, with acceptable inclusion levels up to 500 g per kg.

Lupin meals are used commercially in diets for freshwater, estuarine, and marine finfish as well as crustaceans. This is a small but emerging market, as the relative value of the splits seems high for finfish.

Introduction

The lupin is a legume plant; its seeds have been used as food and feed from ancient times. The green plant itself has been used extensively in some countries as forage and as an organic material for soil enrichment or in crop rotation. Despite its qualities and potential, it has not become a major world crop. This article will review the main characteristics of breeding, the nutritive value of its seeds, and the uses and potential for more extensive production.

The Plant and Its Origin

Lupin or lupine are trivial names for plants of the genus *Lupinus* belonging to the Fabaceae family, subfamily Papilionoideae. This genus is very diverse and contains several known species. It is an annual plant, usually 0.3–2 m in height, with a highly branched stem, digitated leaves, and a shrubby growth pattern. The flowers form high above the leaves, may be of several different colors (white, yellow, purple, blue), and exude a honey-like aroma. The roots are relatively long, usually nodular, and may extend to a depth of 3 m. The lupin has the ability to fix nitrogen and mobilize phosphorus and other elements by the exudation of citrate to the soil. This is very important for soil enrichment in infertile areas. The pods are normally flat and with a hairy aspect on the outside. They vary in length (4–10 cm) and, depending on the species, have different types of seeds that may vary in size, shape, or color. However, the endosperm is usually yellowish, and the most common seeds are flattened (*Lupinus albus*) or ovoid (*Lupinus mutabilis*) with diameters in the range 2–15 mm. It is a plant well adapted to poor sandy and acid soils and also to high altitudes, and to temperate climates, found in Europe. The most important species that are produced on a commercial scale are *L. albus*, *L. angustifolius*, *L. luteus*, and *L. mutabilis*.

Table 1 Taxonomic and common names of some commercial *Lupinus* species

Species	*Common names*
L. albus[a]	White lupin, Egyptian lupin, tremoço,[b] altramuz[c]
L. angustifolius[a]	Blue lupin, narrow-leafed lupin
L. luteus[a]	Yellow lupin, tremosilla[c]
L. mutabilis[d]	Tarwi, tauri, tarhui, chocho,[c] Andean lupin

[a] Mediterranean origin.
[b] Portuguese name.
[c] Spanish names: altramuz may be used also to designate other species.
[d] Andean origin: tarwi, tauri, and tarhul are from native languages.
Reproduced from Encyclopedia of Food Sciences and Nutrition, 2nd Edition (2003), p. 3623, Elsevier Ltd.

The lupin has its origin in the Old World in the Mediterranean region, as well as in the New World, in North America, and in the Andean highlands. Some representative examples of the former are *L. albus, L. angustifolius*, *L. luteus*, and *L. consentinii*. "Tarwi" is the indigenous name of *L. mutabilis*, which is the lupin species found in the Andes (Table 1). However, there are probably more than 200 wild species, most of them in the New World. *L. albus* was cultivated for human consumption by the ancient Romans, Egyptians, and Greeks; however, due to its bitter taste, the mature seed had to be subjected to prolonged washing before consumption. A similar treatment was also used by the ancient inhabitants of the Andes. The seeds of tarwi were boiled, thoroughly washed in a river for several days, and then suitably cooked for immediate consumption or dried for future use. Presently, several different species of lupins are grown in Europe, some parts of Africa, South America, Australia, and New Zealand, including a number of sweet low-alkaloid varieties which are now commercially available.

General Aspects of Lupin Breeding

Lupin utilization and breeding programs started simultaneously. This explains why *L. albus*, cultivated in ancient Egypt, as well as *L. mutabilis*, an Andean native, have the same nonshattering characteristics. In contrast, the wild forms of both the species have a distinct shattering characteristic. Despite progress in the area of lupin breeding, records of the world

gene resources of the lupin plant are still insufficient and not easily available to plant breeders. This has been recognized as one of the main problems for worldwide lupin cultivation. Detailed information on the features of a particular lupin accession would help breeders. Their particular objective of coordinating specific features of the plant with regional conditions of soil and climate, in order to improve productivity on a commercial level, would be possible. The genus *Lupinus* is very diverse, with many species and varieties originating from distinct regions of the New and Old World. This diversity also contributes to a considerable increase in the difficulties encountered while planning a plant-breeding program. Despite these problems, significant advances have been achieved in the improvement of plant resistance to diseases, in the establishment of stable low alkaloid lines, and in the increase of productivity of the most-used commercial species of cultivated lupins.

Production of lupin may be directed to completely different objectives. It may be used as green forage, particularly for silage making, or for green manuring. In these cases maximum green-matter yield is strongly desirable. The plant when used as green manure improves the soil conditions since it increases the amount of organic matter and also provides accumulation of nitrogen and phosphorus in poor sandy soils. Bitter varieties may be used when the plant is grown for this purpose. However, for ruminant feed, as forage, sweet varieties are preferred due to the low alkaloid contents. Lupin grains are increasingly used as protein supplements for ruminant diet, and in some countries it also finds applications in human nutrition. Breeding for lupin seed production needs a more rigorous selection in order to obtain a satisfactory harvest index, short maturation periods, and disease resistance. Enhanced pod setting and normal branching are also desirable characteristics, particularly to complement short growing seasons found in Mediterranean climates. The high levels of toxic alkaloids originally found in lupin seeds used to be a negative factor to improve the worldwide production. However, low alkaloid varieties have been established for the most important lupin species. The "sweet" forms are natural or induced mutants, that were generally weaker, so backcrossing with more vigorous bitter forms was required to improve them. Several sweet varieties have been established in Germany, Poland, Russia, Australia, and in the last decades in France and Chile as well. Most of them are sown in the spring and the first winter varieties were only more recently obtained in USA, Chile, and France for the species *L. albus*. These varieties are not only resistant to temperatures as low as $-10°C$ but also show high yields up to $7.3\,\mathrm{t\,ha^{-1}}$.

Another significant and more recent advance in lupin breeding was plant selection starting from induced mutations of forms with determined growth or epigonals. This was achieved with different species in Germany, Russia, and Poland. However, these mutants were also too weak and backcrossing with vigorous high yielding forms was necessary. In France and in Chile winter cultivars were obtained that are homogeneous in maturity and easy to thresh, but these varieties maintain their tendency to produce lower yields. This has limited their success when sown in the Spring. An exception is a very early maturing variety created in Denmark, with initial material coming from Belarus. Domestication of narrow-leafed lupin in Australia allowed large-scale seed production for animal feeding as a soybean substitute. In fact, Australia has become one of the biggest producers and exporters of lupin seeds in the world. This work was started by J Gladstones, who was responsible for developing early maturing lupin crop with low alkaloid seeds, but at the same time with non-shattering pods. In his breeding work, in order to distinguish desired plants from naturalized types of *L. angustifolius* which were previously bitter with blue flowers, he selected white flowered plants as a marker showing the desired attributes. Natural mutants were then selected from field populations and were intercrossed in order to combine all desired characteristics. Also, crosses with wild types selected from Mediterranean regions were carried out. The first successful variety obtained was Uniwhite, released in 1967. Many other new varieties have been developed following additional breeding programs. Domestication of rough-seeded lupins was later achieved with *L. consentinii*, and more recently breeding programs have been developed to domesticate *L. atlanticus* and *L. pilosus*. Some rough-seeded lupin species grow wild on Mediterranean soils. These two species show great potential for cultivation in fine-textured alkaline soils since few cultivated species have this characteristic. Work by Buirchell in Australia following previous selection of mutants with low alkaloid content by Gladstones has been developed aiming at domestication of these species. Introgression of domestication genes from previously domesticated *L. consentinii* and induction of domestication genes by means of mutation were the strategies used. Some lines of *L. atlanticus* with domestication characters were selected showing potential for large-scale cultivation.

Resistance to Stress and Diseases

Parallel to the improvement of the yield, great efforts have been made to increase lupin resistance to

diseases. Fungal and virus diseases are the most common forms of lupin crop contamination such as anthracnose, fusariose, and phomopsis. The first caused by the fungus *Colletotrichum gloesporoides* poses the main threat for lupin cultivation. The latter causes a disease called lupinosis that affects animals fed with infected plants. Because anthracnose is a seed disease, the symptoms may appear early mainly showing cankers on the stem and the plant may die even before flowering. Significant advances to improve lupin plant resistance to anthracnose have been achieved particularly for *L. angustifolius* in Australia and *L. albus* in Chile. Selection and intercrossing strategies have helped in developing lines more resistant to anthracnose and gray leaf spot from collaborative work between Australian and American researchers. Varieties derived from wild Mediterranean lupins proved to have moderate resistance to phomopsis. However, until now selected varieties are not completely resistant to the pathogens.

Necrotic and nonnecrotic strains of mosaic viruses may also be responsible for crop damage, but to a lesser extent than fungal diseases. *Pleiochaeta setonsa* is the main cause of the disease brown leaf spot, favored by cool temperatures. Because the incidence of this fungus is more accentuated in crops sown in European autumn, winter lupin cultivars tolerant to frost has been increasingly used in Europe. Rust caused by *Uromyces lupinicolus* affects plantation mainly in warm and dry summer promoting considerable defoliation. In this case, the use of fungicides based on triazole compounds appears to be quite effective to face this problem. *Phorbia platura* is an insect that may have a significant negative impact on lupin crop, particularly the white lupin. The larvae usually promote extensive damage to the roots and hypocotyls, and the systemic use of insecticides is the most effective treatment.

Inadequate climate and soil conditions may cause abiotic stress and produce losses in lupin crop. Frost, inadequate soil pH, and other climate conditions are the main causes. Most of *Lupinus* species are not tolerant to high pH. Above pH 7.5, free lime present in the soil may induce iron chlorosis. However, in low pH, below 4.5, aluminum toxicity may be observed. Some structural characteristics of the plant may help in frost resistance. Large roots, which is greatly dependent on genotype, favor plant survival in intense frost conditions. Vernalization requirements and the plant capacity of hardening leaves are other components of frost resistance.

Germ plasm collections, hybridizations, and mutations have been the main sources of genetic variability applied to lupin breeding up to now. Interspecific crossing has also been a useful tool to improve general characteristics of lupin varieties. This has been possible between species of the same number of chromosomes, e.g., *L. mutabilis*, *L. elegans*, and *L. polyphyllus*. This can be an interesting approach, for example, in the case of *L. polyphyllus*, which has small seeds and a high proportion of hull, but by crossing with *L. mutabilis*, it can produce bigger seeds with increased protein content and less fiber. The interspecific crossing between species of different number of chromosomes has been actively pursued by researchers in Australia using more modern techniques.

The improvement of the chemical composition of the seed has been of increasing importance in the last decades, together with the concept of protein and oil yield per hectare. Until now, the most favorable composition has been achieved with *L. mutabilis*, but the best yield of protein and oil per hectare with *L. albus*. However, within the species, different varieties may show significant differences. In the case of *L. albus*, which commonly contains ~35% of protein, it is possible to establish lines with 38–40% of protein. In the case of *L. mutabilis*, some varieties may have up to 50% protein. More recently, great attention has been directed to other seed components such as carotenoids and omega-3-fatty acids when breeding programs are planned.

Lupin seeds have been increasingly used in feed formulation for fish farming, particularly salmon. Due to overexploitation of marine resources, fish farming seems to be a promising source of protein and oil for human nutrition, and the demand for grains, including lupin, used in the rations will certainly increase tremendously. In human nutrition, lupin seeds are an interesting alternative for diabetic persons due to their carbohydrate composition as well as for those who do not tolerate some other sources of protein of animal or plant origin.

Nutritive Value

Lupin seeds show similar nutritive attributes to soybeans, particularly with respect to protein and fat content. Some species may have protein contents up to 50 g per 100 g and up to 22 g per 100 g of fat in the seeds. The approximate composition of seeds of some relevant lupin species are presented in Table 2. The protein and fat content may be further increased by de-hulling the seeds.

Although nutritive value may be theoretically improved by breeding, the immense chemical diversity of compounds that are considered make this task extremely complex. However, if a specific target is chosen, improvement may be achieved through breeding programs based on selection of particular species and varieties and intercrossing with others, which could

lead to promising combinations of characters for cultivation. Because different biochemical pathways are involved in the synthesis of particular nutrients in the plant, in some cases the improvement of a particular nutrient may be deleterious to others. For example, breeding strategies to increase the protein content of a seed may lead to a decrease in the oil levels. In practice, breeding efforts to increase nutrient levels of lupin seed did not appear to have produced effective results yet.

Protein

The lupin seed is one of the richest sources of plant protein. The protein content varies largely between species, with *L. mutabilis* and *L. luteus* presenting unusually high values (near 50 g per 100 g), surpassing most soybean cultivars, whereas *L. albus* presents an intermediate protein content and *L. angustifolius* lower values. Seed protein provides all the essential amino acids, but some of them are not found in sufficient amounts for all sectors of the population. When lupin seed is used for animal feeding, such as ruminants or single-stomach animals, the relatively low level of methionine may be complemented by adequate formulation of the ration or by supplementation with the synthetic amino acid. Table 3 shows the amino acid composition of seeds of some relevant lupin species and the amino acid requirements for infants and adults established by a Food and Agriculture Organization/World Health Organization/United Nations University (FAO/WHO/UNU) joint committee (1985). When comparing the lupin amino acid profiles with the requirements for adults, all lupin species show ranges of essential amino acids with adequate amounts and this will be observed also for most pulses. However, if the requirements for infants are used for comparison, it is apparent that lupin protein will show many essential amino acid deficiencies, with tryptophan being the most limiting, having a chemical score of 47–59%, followed by methionine plus cystine. The chemical score is the ratio of the content of an individual essential amino acids in food protein to the content of the same amino acid in a reference pattern expressed as a percentage. It must be taken into account that, if requirements for infants are used for comparison, even beef protein will be deficient in leucine, lysine, methionine + cystine, tryptophan, and valine, and egg protein will be deficient in leucine

Table 2 Approximate composition of seeds of different lupin species[a]

Species	*TCW (g)*[b,c]	*Protein*[c]	*Oil*[c]	*Ash*	*Fiber*[d]

and lysine. However, if the previous FAO/73 amino acid pattern is used as a reference, methionine + cystine will be the limiting amino acids for lupin (56–71% chemical score), as in most pulses (soybean 83% chemical score). Consequently, it is strongly recommended that the intended nutritional application of lupin seeds or lupin products be defined to allow a more realistic assessment of the protein quality. From Table 3, it can be seen that the amino acid profile varies considerably with lupin species. Large variations are also observed in biological indicators for protein-quality assessment. Nevertheless, protein utilization, as measured by the net protein utilization index, does not correspond exactly to the amino acid chemical score of different lupin species. For example, *L. angustifolius* shows a relatively high chemical score (60%, FAO/85 for infants) but presents the lowest net protein utilization index (43%). Despite its amino acid composition, active biological components appear to have a negative influence on the net protein utilization index of *L. angustifolius* protein in rats. *L. albus* shows the highest net protein utilization index (70%) followed by *L. mutabilis* (64%). These figures approach the net protein utilization index of the soybean (69%). Overall, lupin protein should be considered a good plant source of protein for animal and human nutrition. However, the appropriate application and the variation encountered between species must be considered for assessing lupin protein quality.

Fat

The fat content of lupin seeds varies considerably between species. In some species, the lipid fraction contributes substantially to the total energy value, whereas in others it is present in relatively small amounts (Table 2). *L. mutabilis* has the highest oil content (up to 22 g per 100 g) and is considered to be a potential material for oil production. *L. albus* has a combination of high protein and an intermediate fat content, which are important attributes for a food, especially if it is to be used in developing countries where protein and energy are scarce. The fatty acid distribution in the oil fraction is also variable between species. However, low levels of saturated fatty acids are normally found. A very high content of linolenic acid is present, particularly in *L. albus* and *L. luteus*. As in other seeds, high levels of oleic acid are common for all species, particularly *L.albus* and *L. mutabilis* (Table 4). The ratio of polyunsaturated fatty acids (PUFAs) to saturated fatty acids (SFAs) in lupin seeds is in the range 1.3 to 2.9:1 which is considerably higher than beef but lower than the soybean (4 : 0). Higher rates are important, since it has been strongly recommended that a reduction of SFAs in favor of an increase of PUFAs in the diet should be achieved, to assist coronary heart disease prevention. Linoleic acid, which is an essential fatty acid, is found in significant amounts in lupin seed, with *L. luteus* being the richest source (44%). Linolenic acid, which is the most important source of ω-3 fatty acids, is found at very high levels in *L. albus* and *L. luteus*, but at relatively low levels in *L. angustifolius* and *L. mutabilis* (Table 4). *L. mutabilis* may be commercially used for oil production, and its low linolenic acid content, although not so nutritionally important as in other sources, may be advantageous to improve its conservation in comparison with other vegetable oils. Considering the fatty acid profile of lupin seeds, it is noted that *L. mutabilis* and *L. albus* are more similar to peanut oil, whereas *L. angustifolius* and *L. luteus* resemble maize oils, although they differ in flavor.

Carbohydrates

In contrast with many legumes, lupin seeds are practically devoid of starch, and the major carbohydrates in mature seeds are oligosaccharides and nonstarchy polysaccharides, particularly from the cell-wall structure. The oligosaccharides found in the cotyledons are sucrose and nondigestible galactosides of the raffinose

Table 4 Fatty acid composition of lupin seeds in comparison to soybeans

family. The main galactosides present in lupin seeds are raffinose (degree of polymerization (DP) of 3), stachyose (DP of 4), and verbascose (DP of 5) (Table 5). These oligosaccharides are derived from sucrose, with increasing numbers of α-galactosyl units linked to C6 of glucose. They are present in most legumes and are not digested by monogastric animals and hence contribute to the flatulent property of legumes. More recently, nondigestible sugars have been used as agents for fermentation in the intestines, thus helping to maintain and regulate the microbial intestinal flora. In this aspect, lupin may be an important raw material for production of oligosaccharides of the raffinose family to be used as functional food ingredients. The polysaccharides are present as major components of the cell wall surrounding the cytosol. Only a small number (1%) of polysaccharides are water soluble, and, together with oligosaccharides, they are important as a source of energy for seed germination. The amount of polysaccharides in lupin seeds is dependent on the species, with high contents found in *L. albus* and *L. angustifolius* and the lowest in *L. mutabilis*, due to its thinner seed hull. Due to the polysaccharide composition, lupins are extraordinarily rich sources of fiber. Crude fiber data are presented in Table 2, but even higher figures will be encountered if dietary fiber is considered. Lupin carbohydrates are important sources of energy only for ruminants, but due to their characteristics they may provide useful material to produce special high-fiber food for humans.

Vitamins and Minerals

The vitamin pattern of lupin seeds is somewhat similar to other legumes. Lupin seeds are good sources of vitamins of the B group, particularly niacin, with levels above 4 mg per 100 g. The thiamin content is ~0.5 mg per 100 g and that of riboflavin ~0.4 mg per 100 g. Carotenoids and tocopherols are present, with the former being mainly responsible for the color of the oil fraction. The mineral composition is similar to other legumes in relation to the major elements, except for calcium, which is low in all species. However, some differences are found in respect to trace elements. Manganese is found in lupins in unusually high amounts, especially in *L. albus*. In some varieties of this species, it may reach values of 83.5–143 mg per 100 g, and this must be taken into account when it is used in daily animal or human diet. Nevertheless, common figures are in the range 2.5–38.0 mg per 100 g. Lupin seed is also a good source of iron and zinc, with values in the range 2.5–14.0 and 3.0–18.0 mg per 100 g, respectively.

Bioactive Compounds

Some components found in natural products may present biological activity but no nutritional properties. In fact, some of them may be undesirable for human and animal nutrition. In lupin, some compounds with these characteristics have been reported. Compounds sometimes called "antinutritional factors" are present in lupin seeds in the same range as in other legume seeds, except for trypsin inhibitor, which is virtually absent in the lupin. Allergenic proteins that may cause allergenic food reactions sometimes observed in children are less intense with lupins than with other legume seeds and cow's milk. However, because peanut allergies are quite common, further studies are needed to check if there is any peanut-lupin cross-allergy when lupin is used as an ingredient of mixed flour. Some relevant bioactive compounds found in lupin are the alkaloids, phytates, saponins, tannins, and flavonoids. Those bioactive compounds which were usually called antinutritional factors could be considered as targets for breeding programs. This, in fact, happened with the lupin alkaloids. Intensive breeding work was carried out in different countries based on classical methodologies of plant hybridization and selection and they have succeeded in the development of commercial lupin lines with low levels of alkaloids, the sweet lupins. In relation to other antinutritional factors, the situation is quite different. In fact, a lot of controversy exists at the moment in relation to the properties of these compounds.

Table 5 Oligosaccharide composition of seeds of different lupin species[a]

Species	*Sucrose*	*Raffinose*	*Stachyose*	*Verbascose*	*Galactosides*
L. albus	2.9	1.0	6.6	1.1	8.7
L. angustifolius	3.4	1.5	5.2	2.0	8.7
L. consentinii	2.6	0.9	4.9	0.9	6.7
L. hispanicus	0.7	0.9	6.6	1.8	9.3
L. luteus	1.7	1.2	4.9	4.1	10.2
L. mutabilis	2.4	2.5	8.5	1.1	12.1

Their effects as protective factors for the plant, combined with some confirmed desirable biological properties that have been recently reported for humans, complicate the decision to decrease or in fact increase them in the seeds through breeding work. Some examples are the antioxidant properties of phytates, tannins, and flavonoids, the antitumoral properties of trypsin inhibitors, phytates and saponins, and the protection against cardiovascular diseases of tannins and flavonoids. Although no specific lupin variety has been developed yet by breeding that shows considerably lower levels of those bioactive factors except in relation to alkaloids, selection and intercrossing may be applied to establish lupin lines containing low levels of antinutritional factors. However, it appears that plant transformation would present more potential to show positive results in a shorter time. Current practices based on the use of *Agrobacterium tumefaciens* vectors, direct uptake into protoplasts, electroporation, and microprojectiles have potential as techniques to be used to introduce specific DNA in the lupin in order to block the expression of a specific bioactive compound. The effect which this could produce in the performance of the plant in the field is still something to be seen in the future.

Alkaloids

The major alkaloids present in lupin are from the quinolizidine family, although some gramine alkaloids may also be found in *L. luteus*. Quinolizidine alkaloids have received much attention, because they have a strong bitter taste and may be toxic in high doses. Lupanine, sparteine, lupinine, and some forms of hydroxylated lupanine are some relevant examples. They have a sedative effect on the central nervous system, with sparteine producing the strongest effect. The total alkaloid content in bitter lupins is usually in the range 1.0–4.5 g per 100 g. Intensive breeding work carried out, mainly by Sengbush in Germany, Gladstones in Australia, and Baer in Chile, has led to the establishment of new lupin varieties practically devoid of alkaloids. Presently, sweet varieties of *L. luteus*, *L. angustifolius*, *L. albus*, *L. mutabilis*, *L. consentinii*, and *L. atlanticus* are defined, of which the first three are commercially productive. However, bitter lupins are still largely used in some regions where the new sweet varieties are not well adapted. In those cases, the preliminary soaking and washing procedure before consumption is essential.

Phytates

Phytate is sometimes considered an antinutritional factor, because it is implicated with the impaired absorption of minerals. It is found in lupin seeds roughly in the same concentration range as in other pulses, but it is usually lower than that found in soybeans. The average amount found in lupin seed is ~0.8 g per 100 g. The phytate:zinc molar ratio, which may be an indication of zinc bioavailability, is generally lower than in other legume seeds, making lupin a better dietary source of this mineral. The enzymatic degradation of phytate in the digestive tract or in food products submitted to special processing may lead to the formation of inositol phosphates with different degrees of phosphorylation. Some of these derived components may be detected as phytates by nonspecific methods, although they may not present mineral chelation activity. Consequently, more comprehensive information on inositol phosphate composition of different food items is becoming more important to assess the real role of food phytate in the daily diet. More recently, some attention has been directed to the desirable properties of phytates, particularly due to its antioxidative characteristics, which may be beneficial to counteract free-radical activity. Other biological properties may be derived from the lower inositol phosphates since some of them are involved in cell-signaling mechanisms.

Saponins

Saponins are compounds formed by triterpenoids or steroidal aglycones and a carbohydrate moiety by ester or ether linkages. They are present in different classes of plants, particularly in legumes, roots, and some medicinal herbs. Their presence in food products has been considered to be deleterious if consumed frequently. They are toxic to fish and promote retardation of growth in livestock and laboratory animals. They may also produce erythrocyte lysis *in vitro* and may alter intestinal epithelium functional making the mucosa more permeable. Consequently, their continued use in the diet may jeopardize the process of nutrient absorption. Conversely, it has been claimed that they can also be beneficial since they show the ability to lower plasma cholesterol, they have anticancer activity, and they may act as an inhibitor of viral replication. It is not yet clear, though, whether the net effect in the diet would be negative. Some lupin species such as *L. luteus*, *L. mutabilis*, and *L. angustifolius* may present a saponin content of 57–470 mg per kg, but they are not present in *L. albus*. However, these figures are still low compared to the content present in soybeans, which present values in the range 2000–5000 mg per kg.

Tannins

Tannins are complex polyphenolic substances found in plants, particularly pulses, with the property to precipitate proteins in aqueous medium. They interact with one or more protein molecules forming large cross-linked complexes that are insoluble in water. This property makes food tannins undesirable since they will make part of the dietetic protein indigestible. There is a wide variation on the content of tannins in legume seeds with higher values being found in faba bean and in peas. Lupin seeds present relatively low values of tannins in the range 0.2–0.5%. No correlation has been found between the tannin content and the bitter taste of some lupin seeds, and the impact of tannin from lupin seed in the diet has not yet been demonstrated both in humans or animals. However, the level of tannin in *L. angustifolius* has been considered to be low enough for use in pig diets without any kind of problem.

Flavonoids

Flavonoids are a class of phenolic compounds widely distributed in plants. Quercetin and rutin are among the most largely found flavonoids in a great variety of fruits and vegetables, including tea, coffee, and other grains. As it has been observed with other biologically active non-nutrient components, flavonoids may promote desirable and nondesirable physiological effects in humans. The property of flavonoids to induce goiter has been suggested by studies using peanuts and millet as foods with millet flavonoids presenting a strong inhibition effect on thyroperoxidase activity. The healthy properties of flavonoids may be derived from their antioxidative characteristics as free-radical neutralizers. However, some more specific functions have been reported, including their effect on cancer prevention, antiinflammatory and antiviral activities, and their positive effect on capillary fragility and vascular protection. Data on the presence of flavonoids in lupin are scarce, and although it is not clear whether they are encountered in significant amounts in lupin seeds, different flavonoids have been reported recently in the plants of *L. luteus* and *L. albus*, including those with the aglycones apinegin, genistein, and kaempferol.

Food Uses

At present time, the main applications of lupins are their utilization as green manure and as animal feed. Due to the ability of lupin plants to fix nitrogen and to make insoluble phosphorus available in the soil, they have been increasingly used in the crop-rotation system as an efficient and less expensive means of fertilization. For animal feeding, the whole lupin plant has been used as pasture or forage, or the dry seeds have been used as a direct soybean substitute, or in feeding formulas for pigs, sheep, chickens, dairy cattle, and other livestock. It has been recommended that not more than 10–15% of bitter lupins should be used in pig rations as pigs seem to be more sensitive to alkaloids than chickens. As mentioned earlier, lupin seeds have long been an available protein source for human nutrition. It was a common procedure to submit the grains to prolonged washing to remove the bitter taste, and this washing process is still employed, particularly in some regions of South America where bitter lupin seeds are mainly used. Although the washing process may increase the total cost of lupin products, the water treatment will in fact wash out not only the bitter alkaloids but also the oligosaccharides responsible for the flatulence of legumes. In addition, the end product will show increased relative amounts of protein and oil, on a dry matter basis, due to differences in component solubilities. It is a common procedure in the Andean regions to use leached and cooked bitter lupin seeds directly for consumption as snacks, in soups, salads, and stews. Alternatively, they may be dried and/or milled for future use in several dishes, including baked products. Lupin flour may be used for cereal protein enrichment since lupins and cereals have complementary amino acid compositions. Bread or other bakery products have been made successfully using lupin flour as an additive in the proportion of 10–20%. Many attempts have been made to use lupin seeds as direct substitutes for soybeans, e.g., in fermented products, soy milk, or soybean protein isolate. However, lupin protein does not have exactly the same functional properties as soybean protein, being less stable to heat and forming a milk-like water suspension. Nevertheless, lupin protein may be added to soy products without major modifications to the end product. It is apparent that investigation is still needed to develop a lupin-specific technology and new genuine lupin products for human nutrition.

The Potential of Lupin

The world lupin seed production is at present mainly concentrated in Australia, which has produced 1.38 million ton (Mt) in 1993 and around 2 Mt in the year 2000. This represents 2–4% of the world pulse production. Other lupin producers are the countries of the former USSR, Poland and Germany in Europe, and Chile, Bolivia and Peru in South

America, and South Africa. However, the lupin seed shows a real potential for trade in the grain world market due to its nutritional and agricultural properties. The high alkaloid content that used to be one of the major limitations for a wider application of the lupin seed has been gradually overcome by the introduction of commercial sweet varieties, mainly of *L. albus* and *L. angustifolius*. Although a new sweet variety of *L. mutabilis* is already available, work is still needed to establish a productive line with increased seed size and protein content. Besides the improvement in lupin nutritional qualities, research in specific areas such as plant breeding and biotechnology, crop protection, and food lupin technology is vital for lupin to gain a stronger foothold in the international market, with a substantial increase in production in Europe and South America. To consolidate this status an appropriate international price policy along with a strong marketing strategy is mandatory.

Agronomy

R J French, Department of Agriculture, Merredin, WA, Australia

Introduction

This article surveys the agronomy of the three most commonly grown lupin species – narrow-leafed lupin (NLL, *Lupinus angustifolius* L., also known as the Australian sweet lupin, or blue lupin); white lupin (WL, *Lupinus albus* L.); and yellow lupin (YL, *Lupinus luteus* L.). It describes briefly the Australian and European farming systems in which they are grown, why each species is grown where it is, and the principles underlying the management of lupin crops. Current agronomic recommendations for growing lupin are also described.

Types of Farming Systems in Which Lupin is Grown

About 85% of the world's lupin is produced in Australia, and ~80% of this is produced in the grain belt of Western Australia, where NLL is grown in rotation with wheat and barley. Throughout the 1990s, canola was also increasingly used in rotations . Lupin is grown mostly on deep, coarse-textured (<10% clay), mildly acid soils which, in their natural state, are very infertile. NLL is an ideal grain legume under these circumstances because it is deep-rooted, quite acid-tolerant (as is its associated *Bradyrhizobium*), and modern cultivars yield well. It is preferred on these soils to field pea, the other major grain legume grown in Western Australia, because, despite producing less valuable grain, its strong erect stems and robust stubble mean that it can be harvested readily with machinery used for cereals, and it protects the fragile soil from erosion during long, dry, windy summers.

Lupin does not yield as well as wheat in this system, and farmers do not generally make as much money per hectare from lupin as from wheat. However, lupin contributes indirectly to the productivity of other farm enterprises. Important contributions include providing fixed atmospheric N_2 for subsequent crops, breaking disease cycles in other crops, and providing high-quality supplementary feed for sheep over summer. In the early days of the Western Australian lupin industry, being able to use highly effective selective grass herbicides was an advantage, resulting in much fewer grass weeds in a crop following lupin than following wheat. Western Australia's worst agricultural weed, annual ryegrass (*Lolium rigidum* Gaud.), has since developed widespread resistance to many of these herbicides, and NLL's poorer competitiveness with ryegrass, compared to wheat, is a disadvantage to some farmers. Much of this also applies to other areas of southern Australia, where substantial areas of NLL are grown. However, NLL is not as prominent as in Western Australia, largely due to soil differences.

Outside Australia, the most commonly grown species is WL. The most sophisticated industry based on this species is in Europe, largely in France, where it is grown in rotation with cereals and oilseeds on neutral to mildly acid soils. WL is preferred to other lupin species because, if it is sown early enough in autumn, the vegetative crop can survive the winter in much of the UK, France, and even in parts of Denmark. NLL and YL do not tolerate freezing and in many areas of Europe can only be grown when planted in spring.

There has recently been renewed interest in lupin in Europe with the release of more agronomically suitable varieties and increased emphasis on protein crops in general. However, European farmers face much the same constraints as their Australian counterparts. In a survey of farmers' attitudes to grain legumes (of which lupin is one) in six European countries, rotation and soil improvement was given as the major reason for growing them, and poor profitability in relation to other crops, particularly cereals, as the main reason for not growing them.

The species *L. mutabilis* Sweet., known locally as "tarwi" or "chocho," has been grown and consumed by the inhabitants of the Andean regions of Peru and Ecuador since pre-Columbian times. Attempts to develop this species for commercial crop production outside the Andes have had limited success, and commercial lupin production in Chile is based on WL and NLL.

Growing a Lupin Crop

Which Species?

The species generating the greatest income will generally be chosen. There is little evidence that rotational benefits differ between lupin species, so this will be determined by grain yield, grain price, and the cost of production.

Grain yield is a consequence of adaptation. John Gladstones identified NLL as having wider physical adaptation than other lupin species in Western Australia in the 1950s, and the considerable effort that has gone into its improvement has only reinforced its advantages over WL and YL. There are instances, though, where other lupin species might be grown in Australia. WL is more competitive with NLL on fertile loamy soils than on sandplain. YL tolerates soil aluminium (Al, the major constraint to plant growth on strongly acid soils), waterlogging, and the diseases brown leaf spot (caused by *Pleiochaeta setosa* [Kirchn.] Hughes) and Eradu patch (caused by an as yet unnamed species of *Rhizoctonia*) better than NLL or WL. In central and eastern Europe considerable effort has gone into improving YL which is adapted to the sandiest and most acid soils, so it has predominated until recently. WL tolerates soil freezing better than YL or NLL, so it can survive the northern European winter. This allows it to be sown in autumn, which results in higher yields than spring sowing. NLL has the advantage of greater anthracnose (*Colletotrichum gloeosporiodes* [Penz.] Penz. & Sacc.) tolerance.

Although WL is a minor component of traditional cuisine in some Mediterranean countries, and some components of lupin fiber and protein are being developed as additives for the food industry, lupin grain is mainly used to feed livestock, so the price it

commands should reflect its composition. YL contains more protein than WL, which in turn contains more protein than NLL. YL also contains more S-amino acids, typically deficient in legume storage proteins, than WL or NLL. Consequently YL attracts a higher grain price than WL or NLL, but in Western Australia this is barely sufficient to induce farmers to grow it in preference to NLL, given the lower yield potential of current cultivars. WL has higher oil in its grain, and therefore has greater metabolizable energy than YL or NLL.

Lupin species, and cultivars within a species, may differ in their cost of production. Differences in disease tolerance may mean that one species may not need fungicides necessary for other species. Differences in aphid attractiveness are important in Western Australia: the only agronomically adapted YL cultivar is extremely sensitive to aphid feeding damage, making necessary at least one, if not two, more insecticide sprays than NLL would need.

Sowing Time

Sowing at the correct time is crucial to growing a successful crop, but there are different constraints on sowing time in different parts of the world. In the Mediterranean environments of southern Australia, matching the crop's life cycle to the rainfall pattern is the most important consideration. In early autumn, the soil is typically too dry to support plant growth until the season "breaks" with the onset of winter rains. A cool, wet winter follows; in spring, temperature rises rapidly and rain ceases. To maximize the time available for crop growth, lupin should be sown to germinate on the earliest winter rains. Delaying sowing will mean that the reproductive growth occurs under hotter, drier conditions. This reduces lateral branch production and hence pod numbers, curtails seed filling, and reduces yield. In much of Western Australia's agricultural areas, delaying sowing at the beginning of winter results in a linear yield decline, with a slope as high as 40 kg ha^{-1} day^{-1} (Figure 1). The yield penalty for delayed sowing is usually, though not always, greater in high yield potential situations.

Early sowing has been a central dogma of lupin growing in Western Australia, and sowing the crop into dry soil, anticipating the break of season, is widely practiced. However, there are good reasons for not sowing too early. In eastern Australia, and the south of Western Australia, sowing before the end of April encourages excessive lateral branch growth at the expense of pod set, especially in older cultivars. In drier environments, the first winter rains are sometimes followed by a long period without further rain, severely stressing the young crop. In extreme cases the crop may die, but more often the potential to form lateral branches is restricted and the crop is shortened, which makes complete yield recovery while harvesting difficult. The probability of this happening is low if there is already water in the soil from summer rain. An increasingly important reason for not sowing too early is the developing resistance of important weeds to selective herbicides. As the effectiveness of selective herbicides wanes, alternative methods of weed control must be sought. One is to wait after the season breaks until weeds germinate, and then kill them with a nonselective herbicide, or cultivation, before sowing the crop.

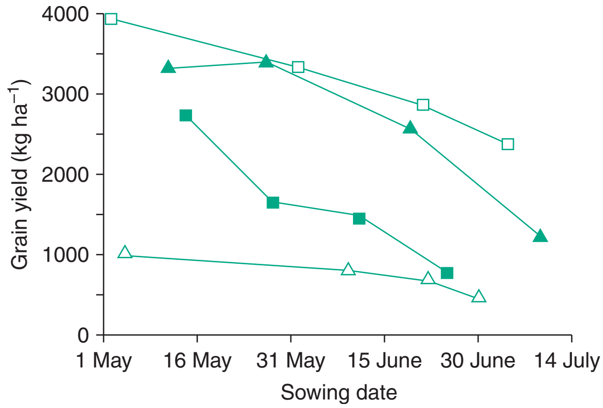

Figure 1 Grain yield response of NLL cultivar Belara to sowing date at four locations in Western Australia: closed squares – Esperance 1998, closed triangles Wongan Hills 1998; open squares – Mingenew 2000; open triangles – Merredin 2000.

In northern Europe, sowing time is chosen so that the crop either survives, or avoids, the harsh winter. When WL plants are old enough, their roots are sufficiently lignified to survive soil temperatures as low as −3.5°C, which would kill younger plants. As the plants age further, and stem elongation begins, the stems become frost sensitive and can be killed by aerial freezing. WL sown too early in autumn also tends to produce too many lateral branches at the expense of pod set, and to grow too tall so that the crop lodges. Physiological models of lupin development have been used to define sowing windows for different locations in the UK, where the sowing window extends from mid-August to early September in Scotland; and from early September to early October in south-west England.

Many of the YL and NLL cultivars grown in Europe have a vernalization requirement for flowering and must be sown early enough in spring to satisfy it. In Germany and Poland, they must be sown before mid-April to ensure that they flower at the correct time and are ready to harvest in August. If sown later, they will be taller and more prone to

lodging, have fewer pods and lower yields, and exhibit delayed ripening. This will interfere with sowing winter wheat, which usually follows lupin, in September.

Optimum Plant Densities

Plant density has a profound effect on the growth and structure of lupin crops. The same general principles apply to each lupin species and in each growing environment, but the target densities may be quite different.

Dense lupin crops achieve canopy closure faster than thin ones, and therefore intercept more radiation earlier, grow faster, and compete with weeds better. Increasing plant density suppresses lateral branch growth and pod set on low-order branches so the number of pods per plant is reduced, but not usually enough to reduce grain yield per unit area. The relationship between grain yield and plant density is usually asymptotic, often well described by a hyperbola. Grain yield sometimes reaches a maximum and declines at higher densities, though.

In Western Australia, NLL grain yield will sometimes respond to increasing density above 80 plants m^{-2}, and sometimes the response is saturated at less than 40 plants m^{-2} (Figure 2). Generally, yield will respond to higher densities when yield potential is high, but there are exceptions.

Modern NLL cultivars are more responsive to plant density than older ones, and Western Australian farmers plant denser lupin crops now than in the past. A target of 50 plants m^{-2} is common. In Germany, sowing 80–100 seeds m^{-2} is recommended for YL and NLL, although restricted branching NLL should be sown at 120–140 seeds m^{-2}. Spring sown WL should be sown at 60–70 seeds m^{-2}. In the UK, 20 plants m^{-2} is optimum for autumn-sown WL, but sowing 40 seeds m^{-2} is recommended because ~50% of plants are lost over the winter season.

Row Spacing and Seed Depth

Lupin is generally sown in rows with the same machinery used for cereals and oilseeds. In Australia, these rows were traditionally 18 cm apart, but in the past decade many lupins (and cereals) have been sown in wider rows, most commonly 22–25 cm. This trend has been driven by changing herbicide practices in wheat cropping, but lupin can benefit from rows perhaps as far apart as 50 cm. Growing lupin in wide rows means more stubble from the previous crop can be retained, which reduces the spread of the *Pleiochaeta* disease organism. Lupin in wide rows also grows taller due to increased intra-row competition between individual plants, improving harvestability. Some farmers are also beginning to experiment with spraying nonselective herbicide between wide rows to combat herbicide resistance problems. Crop plants are protected by hoods around the nozzles. Finally, some agronomists claim that lupin grown in wide rows exhibits a more efficient pattern of water use than when grown in narrow rows, but this has yet to be firmly established. On the other hand, growing lupin in wide rows could encourage more aphid landings, and hence virus spread, unless sufficient stubble is retained to cover bare ground between the rows, and weeds growing between the rows experience less competition from the crop in wide than in narrow rows. No interaction between response to plant density and row spacing has been observed in either NLL or YL in Western Australia.

Lupin cannot be sown as deep as many other large-seeded legumes. The ideal sowing depth for NLL and WL in Western Australia is 5 cm. They were once commonly sown 2–3 cm deep, but this is now discouraged as it encourages *Pleiochaeta* root rot. YL should be sown no deeper than 3–5 cm in Western

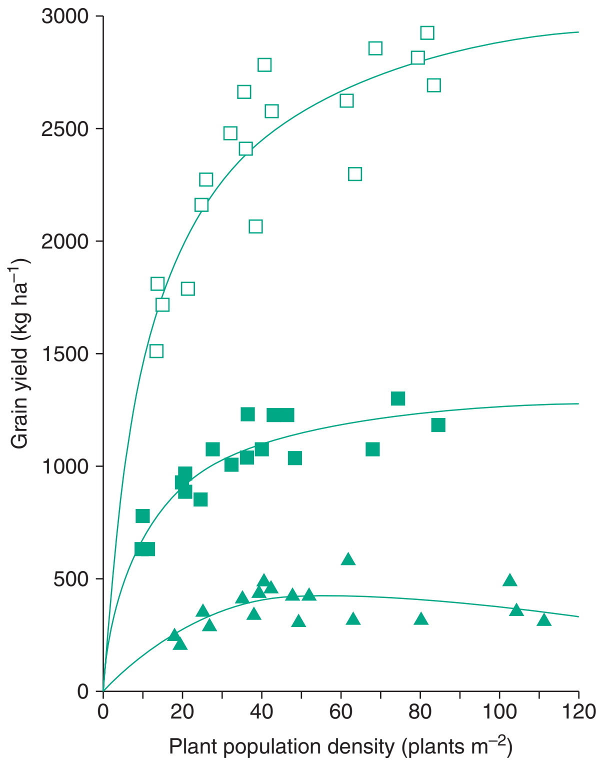

Figure 2 Grain yield response of NLL cultivar Danja to plant population density at three locations in Western Australia: open squares – Beverley 1987; closed triangles – Cadoux 1987; closed squares – Hyden 1988. Australia (Figure 3). In Europe, it is recommended that lupin is sown 2–5 cm deep.

Crop Nutrition

Lupin evolved on very infertile soils and is more efficient at acquiring nutrients than many crops. There is no need to use N fertilizer if the crop is well nodulated. Lupin forms root nodule symbioses with *Bradyrhizobium* species, which do not nodulate other temperate grain legumes. Inoculation of the seed with the appropriate bacterial culture is therefore necessary if lupin is being sown on land without a lupin history. It is rarely necessary to inoculate seed of subsequent lupin crops in Western Australia, even if the previous crop was 5 or more years ago, since lupin *Bradyrhizobium* is very robust on neutral to acid soils. In Germany, inoculation is only recommended for NLL if lupin has not been grown in the preceding 8 years. Seed should be inoculated within a few days of sowing, as the bacteria do not survive well on stored seed, and fungicide seed dressings are usually toxic to the inoculum. There is rarely any advantage in using starter doses of N.

Phosphorus (P) The main fertilizer requirement for lupin in Australia is phosphorus. NLL is more responsive to phosphorus than either YL or WL (Figure 4), which have evolved mechanisms that allow them to solubilize forms of soil phosphorus unavailable to most plants. In these species, phosphorus application is unnecessary unless soil phosphorus levels are very low. In NLL, yield responses have been observed to as much as 40 kg ha^{-1} P on some soils, but farmers in Western Australia typically apply 5–15 kg ha^{-1} P. On the more fertile soils where WL is grown in Europe, it is often most profitable not to apply phosphorus to lupin, and replace the phosphorus it removes elsewhere in the rotation (see Table 1 for the amount of plant nutrients removed in lupin grain).

The way phosphorus is applied can have a large impact on its effectiveness. Australian farmers have traditionally either broadcast phosphorus fertilizer on the soil surface, or drilled it at seed depth with their crops. Many soils quickly immobilize applied phosphorus into insoluble forms and little applied phosphorus reaches the subsoil. It is therefore unavailable to the crop late in the season when the soil surface dries out. This has little effect on cereals, which take up most of their phosphorus requirement early in the season, but NLL maintains a high requirement for phosphorus following flowering. It was discovered in the late 1980s that placing fertilizer up to 10 cm below the seed (called "banding") increased the effectiveness of the fertilizer on high-fixing soils (Figure 4). Banding fertilizer away from the seed is also important when planting lupin in wide rows to avoid toxic osmotic effects of the greater concentration of fertilizer in each drill run.

Potassium (K) and sulfur (S) Lupin grain contains considerable amounts of K (Table 1) but it is usually most profitable to apply it to more responsive crops in the rotation in both Europe and Australia. Increasing amounts of K fertilizer are being used in Australia on cereals and canola but in lupin there have been few economic K responses observed in trials, even where wheat responds strongly. Similarly, lupin appears

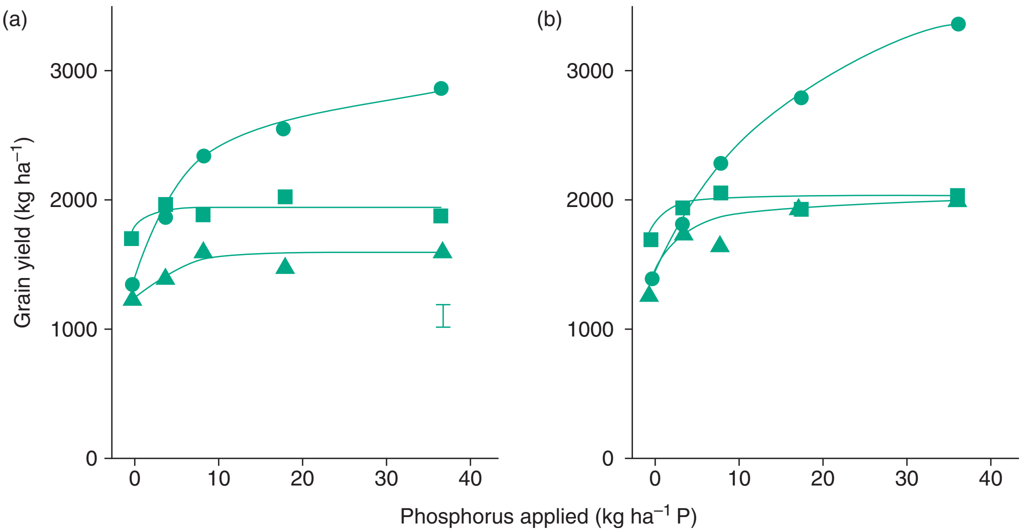

Figure 4 Response of lupin to applied phosphorus on a high phosphorus fixing soil at Mt. Barker, Western Australia. Circles – NLL cultivar Merrit; squares – YL cultivar Teo; triangles – WL cultivar Kiev Mutant. In panel (a) phosphorus was drilled with the seed, in panel (b) it was drilled 8 cm below the seed. (Reproduced with permission from Bolland MDA Sweetingham MW, and Jarvis RJ (2000) Effect of applied phosphorus on the growth of *Lupinus luteus*, *L. angustifolius* and *L. albus* in acidic soils in the south-west of Western Australia. *Australian Journal of Experimental Agriculture* 40: 79–92).

Table 1 Average amount of plant nutrients removed by 1 ton of lupin grain

Nutrient	*Narrow-leafed lupin*	*White lupin*	*Yellow lupin*
Nitrogen (kg)	60	67	70
Potassium (kg)	8.1	9.8	9.7
Phosphorus (kg)	3	3.6	5.1
Sulfur (kg)	2.3	2.4	4.6
Calcium (kg)	2.2	2	1.5
Magnesium (kg)	1.6	1.4	2.1
Zinc (g)	35	30	56
Manganese (g)	17	835	17
Copper (g)	5	5	9

unresponsive to applied S on many soils where wheat is responsive.

Trace elements Manganese (Mn) is the trace element most commonly deficient in lupin. This is principally a problem of NLL, causing "split seed," in which the crop can remain green at maturity and the seed does not develop properly. Both WL and YL are more efficient at acquiring Mn than NLL. In fact, WL grain can have high enough Mn levels to cause nutritional problems when fed to animals. In NLL, Mn deficiency can be treated by applying a foliar application of 4 kg ha^{-1} $MnSO_4$ following flowering. In parts of Western Australia where the disorder occurs frequently, this is routine. Lupin growing on alkaline soils can experience Fe deficiency, but it is rarely grown on such soils.

Weed Management

Lupin is not as competitive against weeds as cereals, and the availability of effective herbicides played a crucial role in establishing the lupin–wheat rotation in Western Australia. Without herbicides early sowing would be impossible since crop establishment would have to wait until germinated weeds could be killed by cultivation.

Any weeds growing prior to sowing the crop are controlled with a nonselective herbicide or by cultivation. Most lupin crops in Australia have simazine, or a combination of simazine and atrazine, applied prior to or immediately after sowing. The safe rate depends on soil type and weather conditions. NLL is more tolerant than YL or WL, and modern cultivars are more tolerant than old ones, having been selected against a background of herbicide use. There are also a number of herbicides that can be applied postemergent to lupin crops. Table 2 gives a list of herbicides used for weed control in lupins in Australia and Europe.

The heavy reliance on herbicides in the Australian lupin-based farming system has encouraged the development of increasingly severe herbicide resistance in some of its most troublesome weeds, most notably annual ryegrass and wild radish (*Raphanus raphanistrum* L.). Considerable effort is being devoted to developing new weed management strategies to

Table 2 Herbicides used for weed control in lupin

Herbicide	*Places of use*
Preemergent herbicides	
Atrazine	Australia
Glyphosate	Australia, Europe
Paraquat/diquat	Australia
Pendimethalin	Australia, Europe
Simazine	Australia, Europe
Terbuthylazine/terbutryn	Europe
Tri-allate	Australia
Trifluralin	Australia, Europe
Postemergent herbicides	
Diflufenican	Australia
Metosulam	Australia
Picolinafen	Australia
Pyridate	Europe
Simazine	Australia
Various aryloxyphenoxypropionates	Australia, Europe
Various cyclohexanediones	Australia, Europe

Registration details should be checked with the relevant pesticide registration authority. Information on weeds controlled, safe rates and application methods is found on herbicide labels.

complement the existing herbicides, and these should become more prominent over the next decade. Examples include towing a chaff cart behind the harvester to collect weed seed rather than returning it to the ground, "crop topping" where a low rate of nonselective herbicide (usually paraquat) is sprayed onto the maturing crop to disrupt weed seed development, and spraying nonselective herbicide between crop rows using specially shielded nozzles to prevent the herbicide contacting the crop.

Diseases

Brown spot Brown spot, caused by *Pleiochaeta setosa*, was until recently the most damaging lupin disease in Australia, a status it now shares with anthracnose (see below). It is also significant in Europe and other parts of the world. It commonly causes leaf lesions that lead to defoliation and, if severe enough, crop death. The organism can also cause a root rot. The disease can be seed borne, but the main source of infection is spores in the soil remaining from previous infected crops. Seed treatment with dicarboximide fungicides (iprodione or procymidone) provides good protection for up to 6 weeks after sowing, and retention of stubble from a preceding cereal crop prevents spores on the soil surface from being splashed onto lower leaves by rain drops, which is the main way infection spreads. Spore populations in the soil decline over time if lupins are not grown, so the recent trend in Western Australia for longer periods between lupin crops on the same land has contributed to fewer problems with brown spot. The root rot mode of *Pleiochaeta* is managed by sowing deep enough so that developing roots do not come into contact with the concentrated band of spores at the soil surface (hypocotyl tissue is not affected), and by not mixing spores through the top 5 cm of the soil by cultivation. YL is more tolerant of *Pleiochaeta* than NLL or WL.

Leaf rust Leaf rust (*Uromyces lupinicolus* Bub.) does not affect lupin in Australia, but is currently the most common lupin disease in the UK, and occurs elsewhere in Europe, North Africa, and South America. It usually occurs on plants approaching maturity, but is most damaging if infection begins before flowering. A preflowering application of tebuconazole or cyproconazole is recommended in the UK to protect WL against early infection, and a further application may be necessary at the end of flowering. NLL, WL, and YL are all susceptible.

Anthracnose Anthracnose, caused by *Colletotrichum gloeosporiodes*, is the world's most important lupin disease. It is serious in Europe, South America, and, since 1996, Western Australia. It has yet to spread in eastern Australia. Infection is primarily seed borne, but infected plants rapidly produce secondary inoculum, which can be spread through a crop by wind and rain splash.

Its effects are minimized by using disease-free seed but, since in the right conditions damaging outbreaks can arise from less than 1 plant in 10 000, seed should also be treated with thiram or carbendazim. Various foliar fungicides can also be effective against anthracnose, but the economics of these are dubious. In Western Australia, control of naturalized populations of *Lupinus cosentinii*, which can act as another source of infection, is an important component of anthracnose management.

Lupin species differ considerably in their susceptibility to anthracnose. NLL has much greater tolerance than either YL or WL, and this explains why the area of NLL has recently grown at the expense of YL in central and eastern Europe. Within NLL, there is considerable variation in tolerance between cultivars, and in Western Australia this is an important consideration in choosing a cultivar in areas likely to experience an anthracnose outbreak.

Virus diseases The two most important virus diseases of lupin are bean yellow mosaic virus (BYMV) and cucumber mosaic virus (CMV). Within a crop, these viruses are spread from plant to plant by aphids, but the initial source of infection can vary. In YL and WL, BYMV is seed borne, as is CMV in NLL and YL. Plants arising from infected seeds are the

Table 3 Invertebrate pests of lupin

Common name	*Scientific name*	*Type of damage*	*Places of occurrence*
Seedling pests			
Cutworm	*Agrotis* spp.		Australia
Brown pasture looper	*Ciampa aritaria*		Australia
Wireworm	*Agriotes* spp.		Europe
Red-legged earthmite	*Halotydeus destructor*	Feeding on emerged seedlings	Australia
Lucerne flea	*Sminthurus viridus*		Australia
Slugs	*Deroceras reticulatum*		Europe
	Arion hortensis		Europe
Bean seedling maggot or bean root maggot	*Delia platura*	Feeding on root and hypocotyl of emerging seedlings	Australia and Europe
Vegetative and reproductive pests			
Green peach aphid	*Myzus persicae*		Australia
Blue green aphid	*Acyrthosiphon kondoi*	Feeding on growing point and flowers	Australia
Cowpea aphid	*Aphis craccivora*		Australia
Lupin aphid	*Macrosiphum albifrons*		Europe
Thrips	*Frankliniella occidentalis*	Feeding on flower buds and leaves	Australia
	Thrips angusticeps		Europe
Native budworm	*Helicoverpa punctigera* syn. *Heliothis punctigera*	Feeding on pods and seeds	Australia
Mirid bugs	*Lygus* spp.	Feeding on young pods	Europe

initial source of infection: aphids pick up the virus when feeding on them, and carry it to healthy plants. BYMV is not seed borne in NLL, but infected pasture legumes such as red clover and subterranean clover act as sources of the virus, again spread by aphids. CMV does not affect WL.

Management of these diseases involves the reduction of virus source and its spread. Where the virus is seed borne, virus-free seed should be used. Management that encourages early canopy closure, such as early sowing, high sowing rates, and narrow row spacing, is beneficial because they shade out weak virus-infected plants and discourage aphid landing. This reduces the chance of the infection spreading. Cultivar choice is also important since there is variation in both YL and NLL in how readily CMV is transmitted to the seed in infected plants. Spraying aphids to prevent virus spread is rarely economical.

Invertebrate Pests

Lupin crops are subject to damage from a number of invertebrate pests, the most important of which are listed in Table 3. They can all be controlled by chemical pesticides, although this is not always worthwhile economically. There are some differences in susceptibility between species: YL is more susceptible to red-legged earthmite than NLL, which is more susceptible than WL; and YL and WL are both more susceptible to native budworm than NLL is. There are also differences in susceptibility to some pests between cultivars within a species. Some Australian NLL cultivars are more susceptible to aphid damage than others, and the YL cultivar Wodjil is also extremely sensitive to aphids. Correct agronomy can help reduce damage from some pests: planting lupin after pasture increases the chance of damage from red-legged earthmite and lucerne flea, which multiply on pasture plants. Deep-sowing predisposes lupin to damage from bean root maggot, and taking measures to ensure rapid canopy closure reduces aphid damage.

Harvesting

Lupin is harvested with the same machinery (combine harvesters) as cereals. In Australia, this is usually done when the seed is at 12% moisture or drier, but in Europe crop maturity can be slow and sometimes lupin is harvested with moisture as high as 30%. Obviously this grain needs drying before storage. Lupin is sometimes desiccated with diquat in Europe to hasten maturity, but care must be taken that seed growth is sufficiently complete, or the grain may begin to rot in the pod. Desiccation with glyphosate has led to loss of seed viability in Australia.

Harvesting losses are usually greater in lupin than in cereals. Lupin pods are very brittle when dry, and pod-bearing lateral branches must often be cut a long way below the pods. The shaking induced by the cutter bar is an important source of pod loss. Such losses are smaller in restricted-branching cultivars, because they have shorter branches, and can also be minimized by fitting harvesters with double-density knife guards. Another source of loss is the large bulk of awkwardly shaped material that will overflow from the front if not taken into the harvester quickly enough. A number

of modifications have been devised to improve crop flow from the front and reduce the chance of blockages. These include increasing the knife to auger distance, belt fronts, air systems which blow material from the cutter bar towards the auger, and modifications to the table auger itself.

Lupin grain is fragile compared to cereals, and must be treated gently, especially if it is to be used for seed. The drum or rotor speed should be as low as possible and the concave closed only enough to ensure pods are threshed. Harvesting in the early morning or at night reduces the amount of seed damage. It also reduces shattering losses as pods and stems are tougher in the more humid atmosphere. If it is to be kept for seed, grain should be handled as little as possible after harvest, to prevent further mechanical damage. In Australia, though, any green material from wild radish should be removed promptly. Green pods of this weed release toxic isothiocyanates that can dramatically reduce germination percentage.

MAIZE

Contents

Genetics

E A Lee, University of Guelph, Guelph, ON, Canada

Maize (*Zea mays* L. ssp. *mays*), in addition to being an economically important crop plant, is a model plant for studying genetics. The intent of this brief article is to acquaint the reader with some of the unique contributions that maize has made to the science of genetics. Information regarding mode of propagation, controlled pollinations, heterosis, quantitative genetics, and breeding are covered in **Maize**: Breeding. Several excellent comprehensive reviews of the general subject are available. A recent book – "Mutants of Maize" – gives an extensive pictorial overview of numerous maize mutants, while another – "Maize Genetics and Breeding in the 20th Century" – gives an overview of the more prominent maize geneticists of the twentieth century and their contributions to maize genetics.

Origin of Maize

Maize, a diploid plant with 10 chromosomes ($x = 10$, $2n = 20$), is a member of the grass (Poaceae) family, which includes crops such as rice (*Orzya sativa*), wheat (*Triticum aestivum*), barley (*Hordeum vulgare*), sugar cane (*Saccharum* ssp.), pearl millet (*Pennisetum glaucum*), and sorghum (*Sorghum bicolor*). The maize genome appears to be an ancient segmental allotetraploid (i.e., hybridization of two species whose genomes are partially alike). Many genes in maize exist as two unlinked copies (i.e., homologs), each of which occur on duplicated chromosomal segments (i.e., linkage blocks). Over time some of these genes have developed slightly different expression patterns (i.e., paralogs), such as the anthocyanin genes – *colored1* (*r1*) and *colored plant1* (*b1*), or *colored aleurone1* (*c1*) and *purple plant1* (*pl1*). For some of these genes, one copy (i.e., pseudogene) may have become nonfunctional due to mutations. While other homologs have not diverged from one another leading to redundancy, such as the *orange pericarp1* (*orp1*) and *orange pericarp2* (*orp2*) genes. Comparing divergence times for 14 pairs of homologs enabled the maize genome to be subdivided into two subgenomes. Molecular marker studies of the two apparent subgenomes of maize suggest that one of the subgenomes is more closely related to sorghum than it is to the other maize subgenome.

Two contrasting theories regarding the origin of maize existed for many years, the "teosinte hypothesis" put forth by George Beadle and the "tripartite hypothesis" championed by Paul Mangelsdorf. Today, the most widely accepted theory is that maize originated from an annual teosinte (*Z. mays* ssp. *parviglumis*), ~7000–12 000 years ago (teosinte hypothesis). *Teosinte parviglumis* ($x = 10$, $2n = 20$) is a wild grass native to Mexico and Guatemala. Maize × *T. parviglumis* hybrids are completely

fertile, vigorous plants. At the chromosome, gene structure, and nucleotide sequence level, maize and *T. parviglumis* exhibit as many differences as would be observed between any two maize varieties. While 7000–12 000 years is considered an extremely short period of time in terms of evolution, dramatic morphologically changes in plant architecture and kernel structure occurred between maize and teosinte in that time (Figure 1). Genetic evidence suggests, however, that as few as five mutations may be responsible for these dramatic morphologically differences. Two genes have been identified that change maize morphology to teosinte morphology. The *teosinte glume architecture1* (*tga1*) locus controls differences associated with kernel structure and *teosinte branched1* (*tb1*) controls differences in plant architecture (Figure 2a). Both *tga1* and *tb1* are believed to be genes that were important in the domestication of maize from teosinte.

Molecular mapping of the various grass genomes has led to two interesting observations. Gene content of the various grass family members does not vary greatly, even though variation in DNA content is considerable. Most of the differences in genome size are due to variation in the amount of noncoding DNA (i.e., DNA other than genes). Noncoding DNA consists of highly repetitive DNA sequences, made up of fragments retrotransposon sequences. The other observation is that gene order is semiconserved across the grass species. This phenomenon is generally referred to as collinearity or synteny. Chromosomal rearrangements have occurred that break up the

(b) An ear segregating for *anthocyanless1* (*a1*) and *shrunken2* (*sh2*). *a1* and *sh2* are tightly linked (0.2 cM) genes, with *a1* affecting aleurone color and *sh2* affecting starch accumulation in the endosperm. (c) *brown mid-rib3* (*bm3*) mutant leaf on the left and a normal leaf on the right. (d) *lethal leaf spot1* (*lls1*) mutant leaf on the left and a normal leaf on the right. (e) An ear segregating for *opaque2* (*o2*) and normal kernels. *o2* kernels indicated by the arrow are lighter colored with a chalky endosperm. (f) *dwarf1* (*d1*) plant on the leaf and a normal maize plant on the right. (g) Example of a feminized tassel with silk tissues (stigmatic tissues) developing from the male flower. This is due to a mutation in the *tassel seed1* (*ts1*) gene. (h) Culm of a plant with functional *purple plant1* (*pl1*) and *booster1* (*b1*) alleles permitting anthocyanin accumulation in the sheath and leaf tissues. (i) *salmon1* (*sm1*) silks. Nonmutant silks are green. (j) Leaves of a *knotted1* (*Kn1*) plant showing extra cell divisions at the vascular bundles. (k) Ears representing four different *p1* alleles, from left to right *p1-rr* (functional in both pericarp and cob tissues), *p1-wr* (functional only in cob tissues, non-functional in pericarps), *p1-rw* (functional only in pericarps, non-functional in cob tissues) and *p1-ww* (nonfunctional in both cob and pericarp tissues). The first letter in the allele designation refers to functionality in pericarps and the second letter refers to functionality in cob tissues. (l) An ear segregating for the *red aleurone1* (*pr1*) gene. *pr1* kernels are red in appearance while nonmutant kernels are bluish-black. (m) An ear segregating for *collapsed pericarp2* (*cp2*) and nonmutant kernels. *cp2* kernels, indicated by an arrow, are extremely thin poorly developed kernels. (n) *collapsed pericarp2* (*cp2*) seedling on the left and normal seedling on the right. (o) *yellow endosperm1* (*y1*) mutant ear in the lower left corner and a functional *Y1* ear in the upper right corner. (All photos are courtesy of Maize DB.)

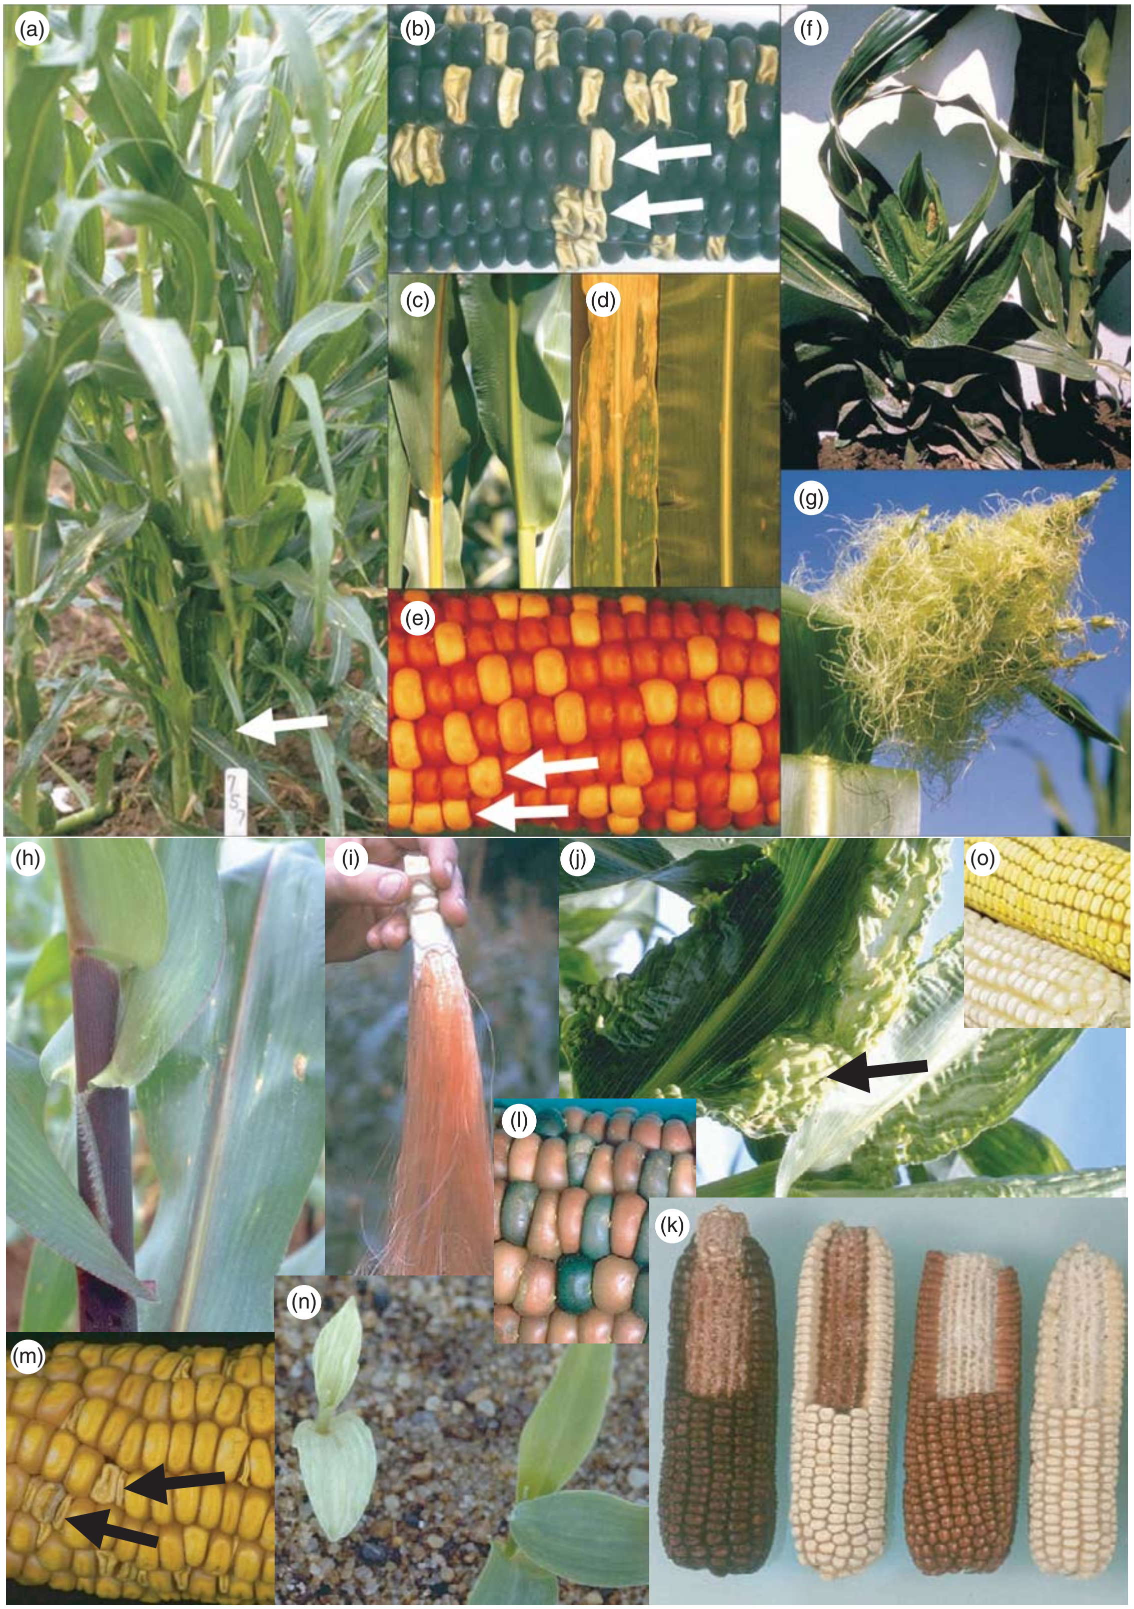

Figure 2

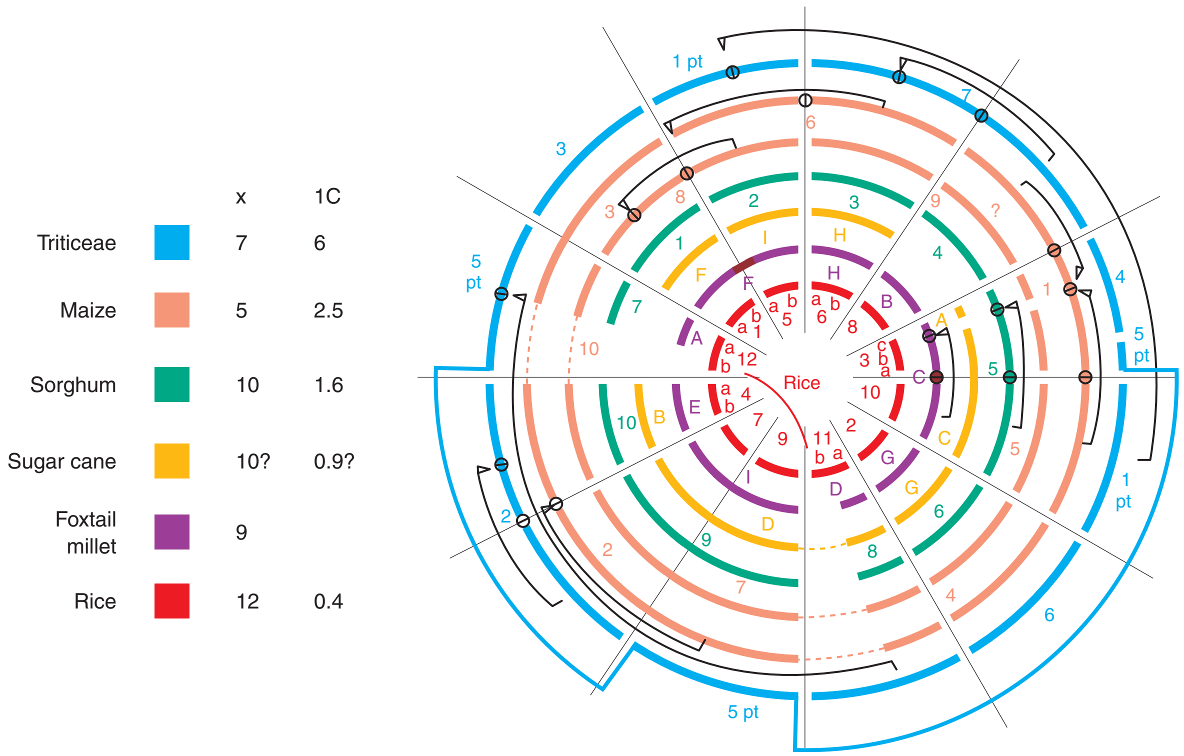

Figure 3 Alignment of the genomes of six major grass crop species with 19 rice linkage segments, whose order reflects the circularized ancestral grass genome. The thin dashed lines correspond to the duplicated segments. Inversions of sets of sequences within a linkage segment (such as the inversion of segments 3a and 3b in maize chromosome 5) are not shown. Linkage segments forming parts (pt) of Triticeae chromosome 5 are shown as a series of segments connected by colored lines. The alignment is based on the genetic map of the D genome of wheat. The red line indicates the duplicated segments shown as blocks 11b and 12b. Chromosomes formed by the insertion of one segment into another are shown by black lines with arrows indicating the direction and point of insertion. The points of chromosome breakage involved with insertion events are indicated by black bisected circles. The "haploid" chromosome number of each species is shown in the column marked "x." The haploid DNA content of each species, shown in the column of 1C values, is per 10^9 bases. (Reproduced with permission from Moore G, Devos KM, Wang Z, and Gale MD (1995) Grasses, line up and form a circle. *Current Biology* 5: 737–739, 169–174. © Elsevier.)

collinearity between grass species. These rearrangements tend to involve translocations, inversions, duplications, or deletions. The syntenic relationships between the maize, rice, and wheat genomes are represented in Figure 3. For example, chromosome 9 of rice contains genes that are contained on chromosomes 7 and 2 of maize, those genes are also found on chromosome 5 of wheat (Figure 3). Generally, collinearity between the grass genomes exists on a macroscale. When collinearity is examined on a microscale, there can be quite a few exceptions to the expected gene order. Synteny is a powerful tool that permits maize geneticists to utilize genetic resources from other grass species. For example, the genome of rice has been recently sequenced. Because of the syntenic relationship that exists between the maize and rice genomes, maize geneticists can potentially identify the rice ortholog for any maize gene and then use the rice ortholog's DNA sequence to isolate the maize gene.

Cytogenetics

Historically, one of the major contributions of maize genetics was to the field of cytogenetics. Maize cytogeneticists were the first to demonstrate that chromosomes are individually recognizable by their lengths, arm ratios, and other physical features, physical exchange of chromosome segments accompanies genetic recombination, and that telomeres are necessary for maintaining fidelity during chromosome duplication and division. Barbara McClintock was the first geneticist to characterize the ten maize chromosomes. Working with mitotic chromosomes, she used initially overall chromosome length and the position of the centromeres relative to each chromosome arm (i.e., arm ratio) to describe each chromosome. Information regarding the presence of chromosome "knobs" (i.e., dark staining heterochromatic regions), nucleolus organizer region (NOR), and chromomeres were later added to McClintock's original description of the chromosomes (Figure 4). The

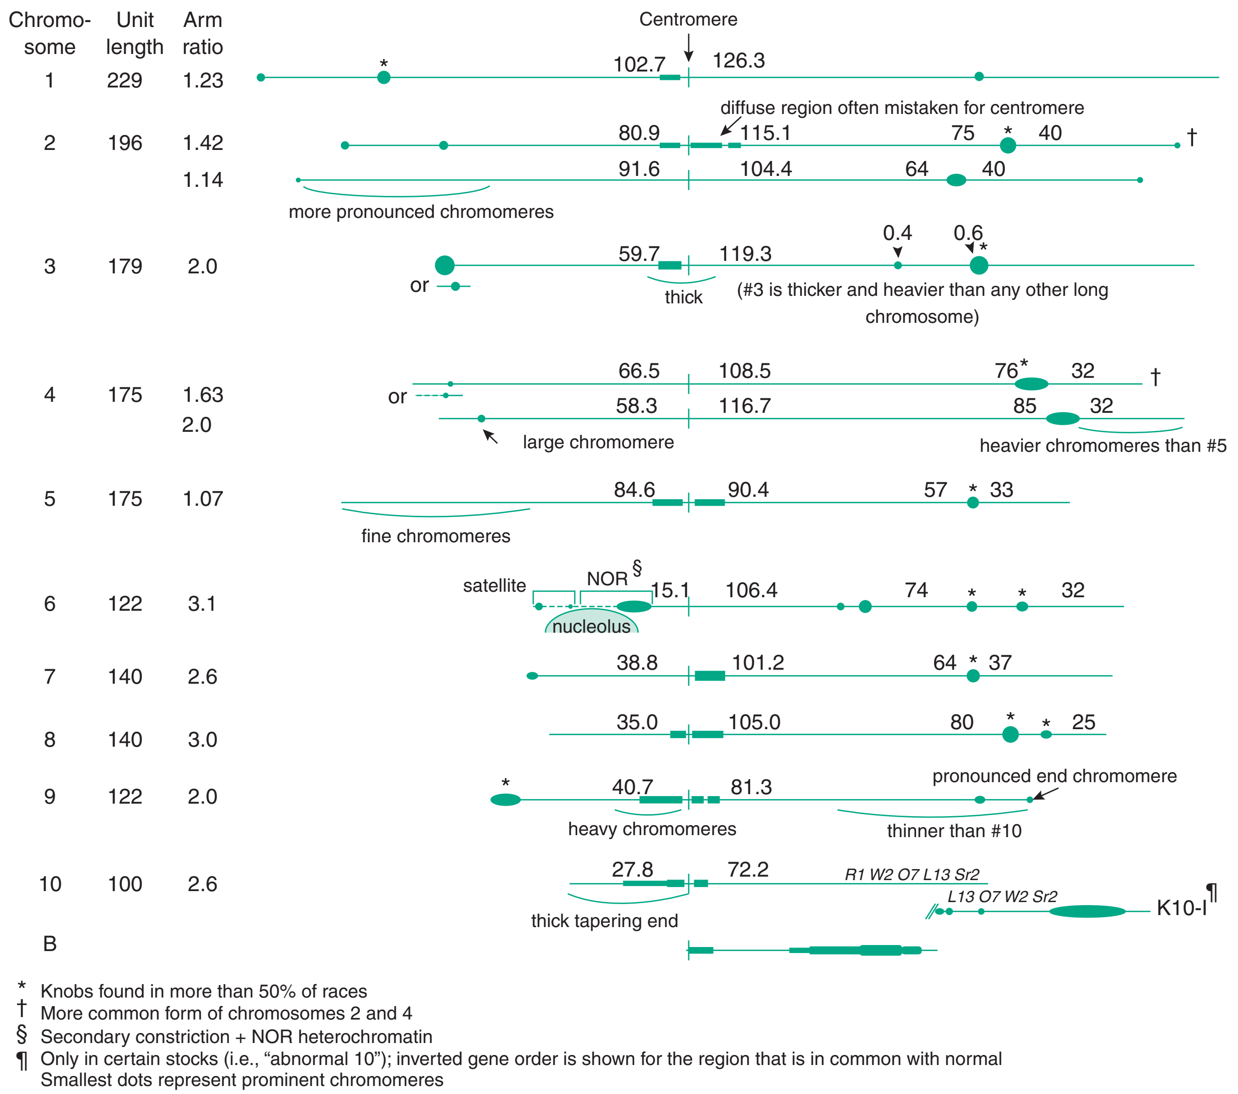

Figure 4 Cytological map of the ten maize chromosomes drawn to scale with major distinguishable features such as arm ratios, chromosome knobs, NOR, and chromomeres. (Reproduced with permission from Neuffer MG, Coe EH, and Wessler SR (1997) *Mutants of Maize.* Cold Spring Harbor, NY: Cold Spring Harbor Laboratory Press.)

maize chromosomes are numbered in order of size, chromosome 1 is the longest and chromosome 10 is the shortest. The NOR region is located at the end of the short arm of chromosome 6.

There are two types of reciprocal translocations that have been developed in maize that have proven to be extremely useful, A–A translocations and B–A translocations. These translocations enabled geneticists to assign molecular marker based linkage groups to chromosomes and orient them, as well as assigning recessive and dominant mutations to chromosome arms. Reciprocal translocations involve exchange of chromosome segments between nonhomologous chromosomes. To create reciprocal translocations requires (1) chromosome breaks to occur in two different chromosomes, followed by (2) rejoining of the fragments to produce two novel chromosomes (Figure 5). The first reciprocal translocations were spontaneous, however most of the reciprocal translocations in maize were generated using ionizing radiation. A–A translocations involve interchanges between the 10 maize chromosomes (i.e., A chromosomes). B–A translocations involve interchanges between one of the 10 maize chromosomes and a supernumerary chromosome called the B chromosome. The B chromosome is relatively small (~60% the size of chromosome 10) and is comprised almost entirely of heterochromatic DNA. There are several interesting features that are unique to the maize B chromosome. It divides normally during cell division (mitosis) and during the development of the megaspore (female gamete). However, its behavior during

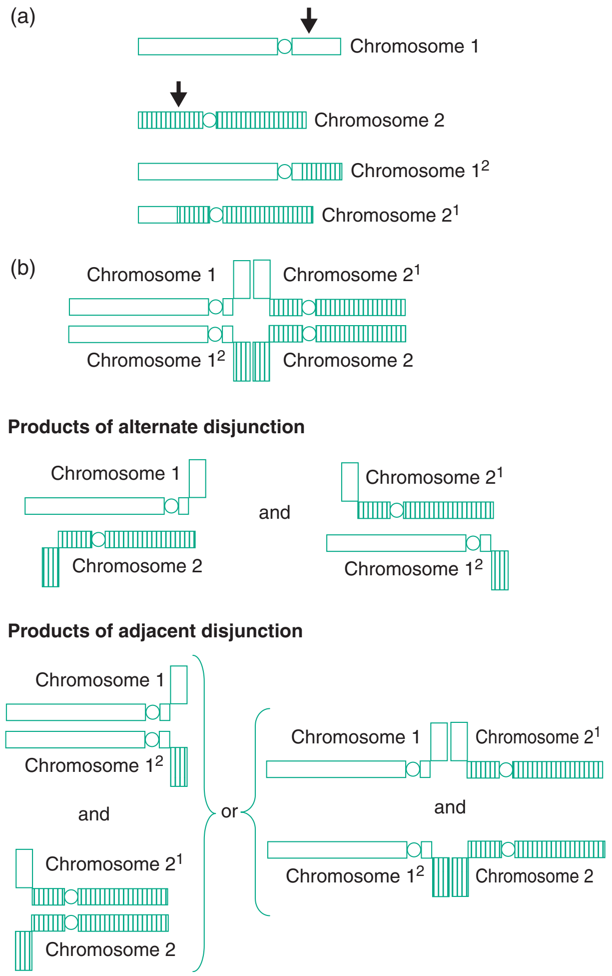

Figure 5 Reciprocal A–A translocations are reciprocal exchanges between two nonhomologous chromosomes (1 and 2). (a) Chromosome breaks occur in the two chromosomes (denoted by the arrows) followed by rejoining of the two fragments to generate two novel chromosomes (1^2 and 2^1). Chromosome 1^2 contains the intact long arm of chromosome 1, along with the centromere of chromosome 1 and a portion of the short arm of chromosome 1, to which is attached the chromosome fragment of chromosome 2. Likewise, chromosome 2^1 contains the intact long arm of chromosome 2, along with the centromere of chromosome 2 and a portion of the short arm of chromosome 2, to which is attached the chromosome fragment of chromosome 1. (b) In meiosis reciprocal A–A translocation heterozygotes (i.e., one copy each of chromosomes 1, 2, 1^2, and 2^1) pair in a Chi arrangement. Only when alternate disjunction occurs are the resulting gametes viable. Adjacent disjunction results in chromosome duplications and deficiencies.

development of the microspore (male gamete) and subsequent fertilization are what distinguish the maize B chromosome from other B chromosomes. (1) Nonconcordance of the two sperm nuclei arising from the second mitotic-like division of microsporogenesis occurs. This phenomenon, also called nondisjunction, is the result of one of the sperm nuclei receiving two copies of the B chromosome while the other sperm nuclei is lacking the B chromosome. (2) The megaspore is preferentially fertilized by the sperm nuclei containing the B chromosomes. These two phenomenon result in an accumulation of B chromosomes in each generation. It is a unique, yet unknown, feature of the B chromosome's centromere that is responsible for nondisjunction and it is this feature that makes the B–A translocations particularly useful for mapping recessive mutations (Figures 6 and 7).

Transposable Elements

Probably the largest contribution that maize has made to the field of genetics was the discovery and genetic characterization of "jumping genes," for which Barbara McClintock was awarded the Nobel Prize in Medicine in 1983. Transposable elements (TEs) (i.e., "jumping genes") are pieces of DNA that can move around the genome. Transposable elements are the single largest component of most eukaryotic genomes, accounting for 50–80% of the DNA sequence in some grass family genomes. However, only a small fraction represent sequences that are still active. The TE that McClintock identified and studied was a site that was vulnerable to chromosome breakage, hence she named it *Dissociation* (*Ds*). *Ds*, however, could break chromosomes and transpose only when a second factor, called *Activator* (*Ac*), was present. *Ac*/*Ds* represent one TE family in maize, *Ac* is the autonomous element (i.e., capable of moving by itself) and *Ds* is the nonautonomous element (i.e., not capable of moving by itself). Part of *Ac*'s DNA sequence contains a gene that encodes an enzyme required for transposition, transposase. The DNA sequence of *Ds* elements is identical to *Ac*, except that the transposase gene is partially or completely deleted (Figure 8).

Transposable elements display some Mendelian properties. They are associated with chromosomes and they can be transmitted from parent to offspring. Phenotypically, their only effect is through their affect on the expression of other genes. Many TEs preferentially insert into genes when they move. The insertion of a TE generally disrupts the gene's normal pattern of expression, for example, altering tissue specificity or knocking out expression altogether. Transposable elements also display some very "non-Mendelian" characteristics. Their genome position is not constant, rather they are capable of moving (i.e., transposing) around the genome. They cause the appearance of variable expression of genes when they "hop-out" of a gene and restore functionality during development. This is normally observed as sectors of expression in cell lineages, either streaks or spots are the common types of sectors observed. The larger the

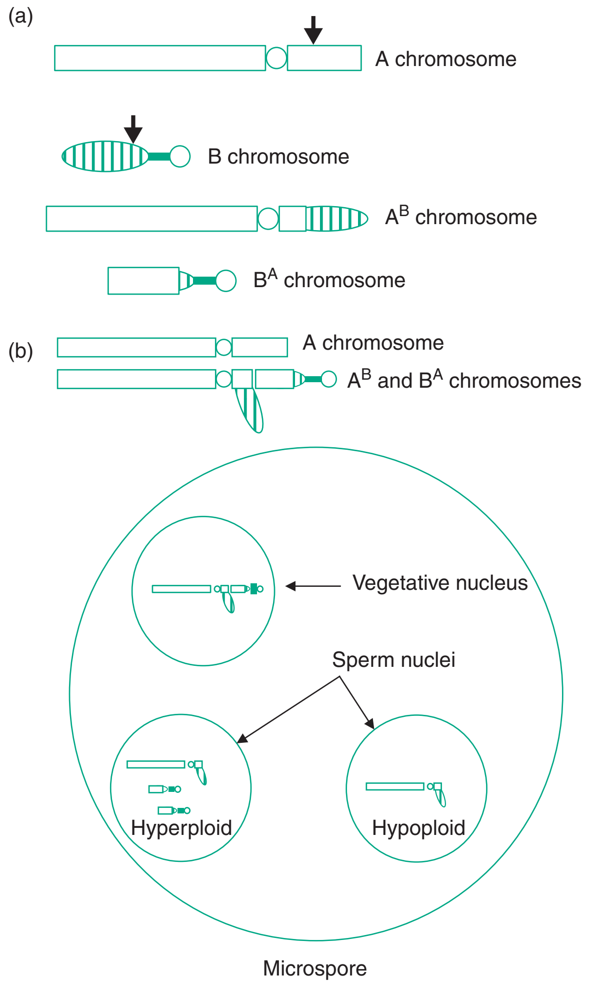

Figure 6 B–A translocations involve interchanges between one of the ten maize chromosomes (A chromosomes) and the supernumerary chromosome called the B chromosome. (a) Chromosome breaks occur in the two chromosomes (denoted by the arrows) followed by rejoining of the two fragments to generate two novel chromosomes (A^B and B^A). Chromosome A^B contains the intact long arm, the centromere, and a portion of the short arm of the A chromosome, to which is attached the chromosome fragment of the B chromosome. Likewise, chromosome B^A contains the centromere of the B chromosome and a portion of the arm of the B chromosome, to which is attached the fragment of the A chromosome. (b) Chromosome pairing in a B–A translocation heterozygote and the consequences of non-disjunction during the second mitotic like division of microsporogenesis. During microsporogenesis, 50% of the viable pollen grains (i.e., microspores) contain the non-translocation A chromosome, but the other 50% of the microspores non-disjunction occurs during the second mitotic like division. After meiosis the microspore undergoes two mitotic like divisions. The first division gives rise to the vegetative and generative nuclei. The vegetative nucleus governs pollen tube development, but the generative nucleus undergoes a second division to give rise to the two sperm nuclei. It is during this second division that the B chromosome centromeres fail to disjoin following duplication. This results in one sperm nucleus lacking the portion of the A chromosome translocated to the B centromere (i.e., B^A), a condition referred to as hypoploidy, while the second sperm nucleus has two copies of B^A chromosome, a condition referred to as hyperploidy.

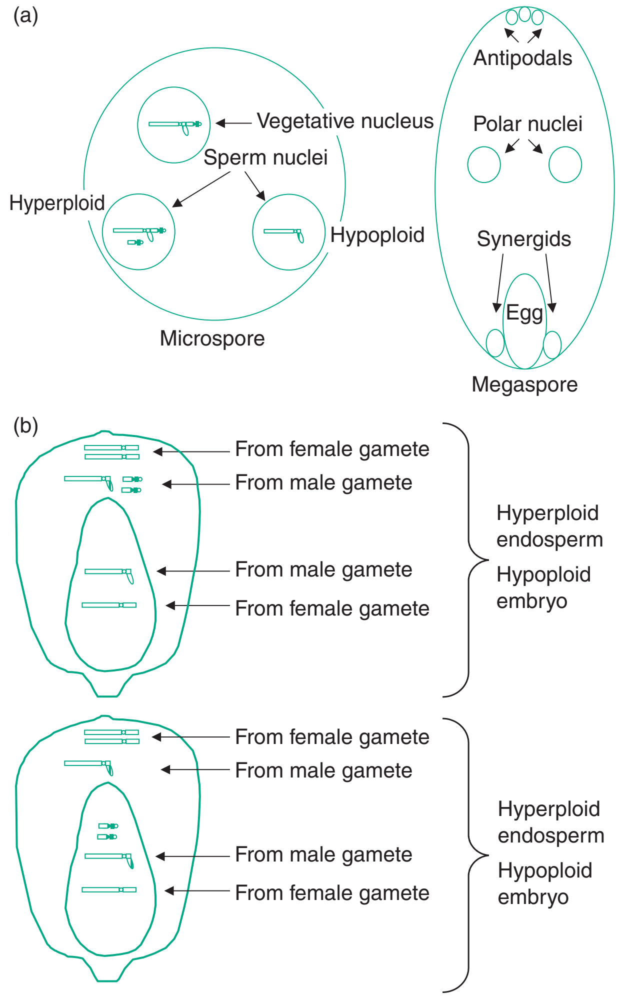

Figure 7 Fertilization of a normal megasporocytes with a microsporocyte containing a B–A translocation. (a) One of the sperm nuclei fuses with the egg to form the embryo (2*n*), while the other sperm nuclei fuse with the two polar nuclei to give rise to the endosperm (3*n*). (b) If the hypoploid sperm nucleus fuses with the egg, any recessive mutations in the female that are present in that A chromosome segment translocated to the B centromere will be visible. If the recessive mutation affects kernels characteristics such as aleurone color or starch formation, then those phenotypes will be visible when the hypoploid sperm nuclei fuse with the two polar nuclei to for the endosperm.

sector, the earlier in development (i.e., establishment of the cell lineage) the TE excised from the gene and restored function (Figure 9).

Mutants of Maize

One of the features that made maize an attractive plant with which to study genetics was the wealth of mutations that visibly alter some aspect of the plant and the ease with which controlled crosses between two genotypes can be made (*see* **Maize:** Breeding). There have been four types of mutants in maize that have been

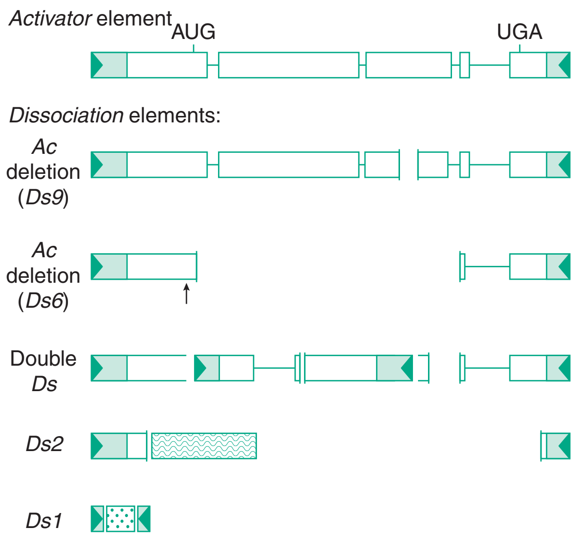

Figure 8 *Ac*/*Ds* family of transposable elements. *Ac* elements are 4565 bp in length, consisting of 10 bp terminal inverted repeats (TIRs) at the ends (green arrowheads), exons (green boxes), introns (connecting lines), nontranscribed regions (green boxes), and one open reading frame (AUG start codon through UGA stop codon) that encodes the transposase. The *Ds* elements are structurally diverse and consist of internal deletions of the *Ac* element. *Ds1* and *Ds2* also contain unique DNA sequences (wavy and dotted boxes). (Reproduced from Neuffer MG, Coe EH, and Wessler SR (1997) *Mutants of Maize*. Cold Spring Harbor, NY: Cold Spring Harbor Laboratory Press.)

extensively studied: those that affect kernel properties, those that affect pigmentation, those that affect plant form, and those that affect fertilization. Several of these mutants have become economically important, such as the genes used in "sweet corn."

Mutants Affecting Kernel Properties

There are two groups of mutants that affect the kernel, mutations affecting carbohydrate, oil, or protein composition and content (Table 1) and mutations that affect kernel development (Table 2). While studying kernel mutations, it is important to remember that the kernel is actually a mixture of maternal tissues (e.g., pericarp) and zygotic tissues (e.g., embryo, aleurone, and endosperm), and that the embryo is diploid ($2n$) while the aleurone and endosperm are triploid ($3n$). The triploid nature of the aleurone and endosperm result from two identical maternal gametes (i.e., polar nuclei, the result of megasporogenesis) fusing with one paternal gamete (i.e., sperm nuclei, the result of microsporogenesis) (Figure 7).

The typical maize kernel is composed of 70–75% starch, 8–10% protein, 4–5% oil, 1–3% sugar, and 1–4% ash. Most of the starch is associated with the endosperm (<90%), while the embryo contains high levels of protein (~26%), oil (~83%), sugar (~70%),

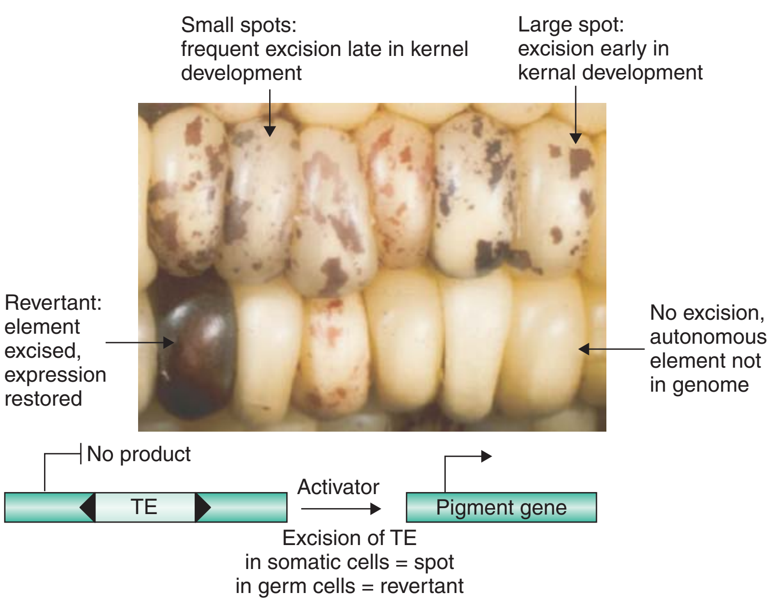

Figure 9 Phenotypes of kernels from a genotype with an *Ac* element in the genome and a *Ds* element inserted in an anthocyanin gene. The kernels represent several different times of *Ds* element excision during development, from extremely early events resulting in completely colored kernels, to mid-development resulting in large colored spots, to late in development resulting in small colored spots. Completely colored kernels are termed revertants, meaning that the TE excised from the germline. Completely colorless kernels indicate that the autonomous element, *Ac*, is not present in the germline, but the *Ds* element is still interrupting the anthocyanin gene in the germline. Spotted or sectored kernels represent somatic excision events and indicate that the *Ac* element is still present in the germline and that the *Ds* element is still interrupting the anthocyanin gene in the germline. Table 1 Mutations affecting carbohydrate or protein composition of the kernel. Mutation abbreviations are in parentheses

Mutation	*Gene product*	*Kernel phenotypic description*	*Economic use*
Carbohydrate composition mutations			
amylose extender1 (*ae1*)	Starch branching enzyme II	Glassy appearance, high amylose content	Highly linear starch used for food, films, fibers, and other industrial purposes
brittle endosperm1 (*bt1*)	Amyloplast adenylate translocator	Collapsed, often translucent and brittle	Used in sweet corn
brittle endosperm2 (*bt2*)	ADP glucose pyrophosphorylase	Collapsed, often translucent and brittle	Used in sweet corn
dull1 (*du1*)	Starch synthase	Glassy appearance	
shrunken1 (*sh1*)	Sucrose synthase	Inflated, transparent kernels collapse on drying	
shrunken2 (*sh2*)	ADP glucose pyrophosphorylase	Inflated, transparent, sweet kernels collapse on drying	Used in "super-sweet" sweet corn
sugary1 (*su1*)	Isoamylase	Wrinkled and translucent	Used in sweet corn
sugary2 (*su2*)	Starch branching enzyme	Glassy, translucent, sometimes wrinkled	
sugary enhancer1 (*se1*)	Unknown	Observed only in *su1* lines light yellow, slow drying	Used with *su1* sweet corn to boost sugar content 50–100%
waxy1 (*wx1*)	NDP-glucose-starch glucosyltransferase	Opaque endosperm, high in amylopectin	Highly branched starch, used for food gels, adhesives, and other industrial purposes
Protein composition mutations			
floury1 (*fl1*)	Unknown	Soft, opaque endosperm	
floury2 (*fl2*)	Alpha zein	Soft, opaque endosperm, reduced protein levels	
floury3 (*fl3*)	Uknown	Soft, opaque endosperm, reduced production of the prolamine fraction, and enhanced lysine content not used commercially due to poor germination	
opaque endosperm1 (*o1*)	Unknown	Soft, opaque endosperm	
opaque endosperm2 (*o2*)	Unknown regulatory protein of zein proteins and *pyruvate orthophosphate dikinase1* (*pdk1*)	Soft, opaque endosperm, higher in lysine and tryptophan	
opaque endosperm2 (*o2*)	Unknown	Soft, opaque endosperm, higher in lysine	
gamma zein modifier1 (*gzr1*)	Unknown	Modifies the hardness of *o2* endosperm	
mucronate1 (*mc1*)	Unknown	Dominant, opaque endosperm, higher in lysine	
proline responding1 (*pro1*)	Unknown	Crumpled, soft, opaque endosperm, proline auxotroph	

Table 2 Mutations affecting kernel development

Mutation	*Gene product*	*Phenotypic description*
defective kernel1 (*dek1*)	Calpain superfamily member	Germless kernel that can not be embryo rescued because only the root primordia are present, the shoot primordia are absent. Floury, white endosperm with missing aleurone layer
dek2 to *dek3*	Not yet identified	Similar to *dek1* above
cp2, cp3	Not yet identified	Collasped pericarp
emp1, emp2	Not yet identified	Empty pericarp
ren1, ren2, ren3	Not yet identified	Reduced endosperm
miniature seed1 (*mn1*)	Cell wall invertase	Small (∼1/5 the size of a normal kernel), fully viable kernel
mn2-cp1	Not yet identified	Small kernel, loose pericarp, defective appearing, but fully viable kernel

and ash (~80%). Mutations that affect kernel composition either can alter total content or composition of the protein, starch, or oil fraction. Starch is a homopolymer of glucose molecules linked together in either α-1,4 or α-1,6 linkages. There are two types of starch molecules.

1. Amylose is a linear molecule composed of α-1,4 glucose linkages. For about every 200 glucose molecules, there will be an α-1,6 glucose linkage that gives the starch molecule a small degree of branching. The amylose molecules are highly variable in length, ranging from 100 to 1000 glucose molecules.
2. Amylopectin molecules are larger, consisting of up to 200 000 glucose molecules and have a higher degree of branching with ~4–5% of the glucose molecules in α-1,6 glucose linkages.

Amylose makes up 25–30% of the starch, while amylopectin comprises 70–75% of the starch in a typical maize kernel. There are two mutations that shift this ratio rather dramatically, *amylose extender1* (*ae1*) results in high amylose content while *waxy1* (*wx1*) results in high amylopectin content. Both the *wx1* and *ae1* mutations are used in specialty maize to produce commercial specialty starches for food and nonfood industrial uses. In addition to these mutations, there are numerous mutations that interfere with starch formation, resulting in "sweet" rather than "starchy" kernels (Table 1). Of these mutations, three are used commercially in "sweet corns" to confer sweetness: *shrunken2* (*sh2*) (Figure 2b), *sugary1* (*su1*), and *sugary enhancer1* (*se1*). The typical fatty acid profile of a maize kernel is 50% linoleic acid, 1% linolenic acid, 40% oleic acid, 12% palmitic acid, and 2% stearic acid. Most of the genetic research on maize kernel oil has focused on total content rather than composition, the inheritance of which is highly quantitative, however, one single gene mutant effecting oil composition has been identified. Linoleic acid content is controlled by a single recessive mutation, *linoleic acid1* (*ln1*). Maize kernel proteins are very high in sulfur-bearing amino acids (i.e., methionine and cystine), but are deficient in the essential amino acids, lysine, and tryptophan. The endosperm contains the gluten proteins, glutelin, and zein. Changes in protein content of a kernel generally involve changes in the gluten proteins, primarily the zein component. Zeins, devoid of lysine and tryptophan, are the proteins that hold the starch granules in a matrix. Increased zein levels are generally associated with an increase in endosperm hardness. There are two families of mutations that affect the zein genes in maize, *floury* and *opaque* (Figure 2e) mutants. These kernel mutants have extremely soft endosperm and are either higher in lysine and tryptophan or have an altered protein profile (Table 1). The *opaque2 (op2)* mutation has been used to develop high lysine specialty maize, referred to as quality protein maize (QPM).

It has been estimated that more than 350 genes affect kernel development. Mutations in these genes generally result in poorly filled, collapsed, crumpled, germless, small, or loose-pericarped appearing kernels, hence the name *defective kernel* (*dek*) mutants. Some of these mutations are completely lethal (i.e., defective kernels will not germinate), others such as *collapsed pericarp2* (*cp2*) are seedling lethals (i.e., defective kernels germinate, but the seedling dies) (Figures 2m and 2n), while other mutations are not lethal (i.e., defective kernels germinate and the resulting plant is fully fertile). Lethal mutations can be further divided into those that can be rescued by excising the developing embryo and culturing it on either basal or enriched tissue culture medium. The rescued embryos produce seedlings that are viable long enough to observe altered seedling phenotypes. The lethal mutations generally represent developmental failures, which are specific to a particular stage of embryo development. For example, *dek1* embryos when rescued will develop into seedlings that are missing the shoots. In other words, the *dek1* mutation interferes with shoot primordia formation, but not root primordia formation in the embryo.

Mutants Affecting Pigmentation (Kernel and Plant)

Phenolic-based compounds and carotenoid compounds comprise two of the major classes of pigments in maize. The phenolic-based compounds arise from the phenyl-propanoid pathway through either the flavonoid pathway or the lignin-biosynthesis pathway. The carotenoid compounds are derived from fatty acids. Carotenoid mutations are visible either through their effect on the accumulation of carotenoids in the kernel (i.e., endosperm color or lack of dormancy of the embryo) or through their effect on chlorophyll stability (i.e., albino, pale green, or delayed greening of seedlings). Some of the mutations affect both endosperm and seedling phenotypes, while others are specific. Endosperm color can be altered from yellow to white by the mutation *yellow endosperm1* (*y1*), that results in a lack of β-carotene (provitamin A) (Figure 2o). This mutation is used commercially to produce white endosperm maize, and subsequently, white starch. In addition to *y1*, there are over 20 genes that alter carotenoid content of the kernel. Some of these genes impart a lack of embryo dormancy (i.e., vivipary), causing mature embryos to germinate on the ear.

The lignin pathway has four mutants associated with it that either reduce the total lignin content of the plant or alter the lignin composition. Lignin is a polymer composed of three different monolignols, *p*-coumaryl alcohol, coniferyl alcohol, and sinapyl alcohol. These monolignols polymerize to form lignin, which is part of the cell wall. Phenotypically, mutations in the lignin-pathway genes result in a browning of the midvein (i.e., midrib) of the maize leaf, hence the name *brown mid-rib (bm1)* mutants (Figure 2c). Economically, these mutants are of interest as a means of increasing the digestibility of the stover that is fed to ruminant livestock. The *bm1* mutant, which encodes the enzyme cinnamyl alcohol dehydrogenase, reduces lignin content of the stover at maturity by ~86%. However, *bm1* does not result in increased stover digestibility. The mutant *brown mid-rib2* (*bm2*) alters lignin composition, greatly reducing the guaiacyl (i.e., polymerized coniferyl monolignol) content, but increasing the levels of the syringyl monolignols. Mutations in *brown mid-rib3* (*bm3*), which encodes caffeate O-methyltransferase, result in increased stover digestibility when fed to livestock. The fourth mutant, *brown mid-rib4* (*bm4*) has not been extensively characterized. The *bm3* mutation is being used commercially in maize hybrids developed specifically for the North American silage market.

Flavonoid mutants were probably the earliest and the most extensively studied set of mutants in maize. The flavonoid pathway in maize produces at least four types of flavonoid compounds: flavones, flavonols, anthocyanins, and phlobaphenes. Only the latter two are visible compounds. Anthocyanins are blue/black pigments and phlobaphenes are reddish-brown pigments. The flavonoid pathway branches off the phenyl-propanoid pathway at the 9-carbon compound, 4-coumaroyl CoA. Chalcone synthase, regarded as the first committed step in the flavonoid pathway, is responsible for the synthesis of chalcone from three molecules of malonyl-CoA and the 9-carbon phenyl-propanoid pathway product. Maize has two genes that encode chalcone synthase, *colorless2* (*c2*) and *white pollen1* (*whp1*). *c2* and *whp1* are examples of homologs that have evolved slightly different expression patterns. Only *c2* is expressed in the aleurone, while both *whp1* and *c2* are expressed in cob, pericarp, and other plant parts. The effect of the *whp1* mutation on pollen color is only observed when *c2* is nonfunctional. Mutations in both flavonoid-pathway structural genes, such as *c2*, and regulatory genes have been identified. In addition to *c2* and *whp1*, mutations in the structural genes *a1* (Figure 2b), *a2*, *bz1*, *bz2*, *pr1* (Figure 2l), *sm1* (Figure 2i), and *sm2* have been identified (Table 3). These mutations have been ordered in the context of the flavonoid pathway, in some instances appearing to be involved in multiple branches of the flavonoid pathway. The regulatory genes governing the flavonoid pathway are composed of primarily myb-like (*c1*, *pl1*, *p1*, and *p2*) and myc-like (*r1*, *b1*, and *in1*) oncogene transcription factors (Table 4), and unlike the structural genes, appear to be relatively pathway-branch specific. For example, *r1/b1* and *c1/pl1* are only involved in activating the anthocyanin branch of the pathway. But activation of the pathway requires both the presence of a functional *r1* along with a functional *c1* for aleurone pigmentation, and *b1* with *pl1* (Figure 2h) for plant pigmentation. *p1* is responsible for activation of the phlobaphene pathway, with various alleles of *p1* imparting to tissues specific expression of the phlobaphene pathway (Figure 2k).

Mutants Affecting Plant Form

There is an impressive array of mutations that affect plant form. For example, the *dwarf* (*d*) mutations affect plant stature (Figure 2f), the *lesion mimics* (*les*) mutations mimic leaf diseases (Figure 2d), the

Table 3 Mutations affecting the flavonoid pathway structural genes

Mutation	*Gene product*	*Phenotypic description*
anthocyaninless1 (*a1*)	NADPH dihydroflavonol reductase	Colorless aleurone, when all other anthocyanin factors are present, brown pericarp and cob tissues with p1 alleles that function in pericarp and cob tissues
anthocyaninless2 (*a2*)	Leucoanthocyanidin dioxygenase	Colorless aleurone, when all other anthocyanin factors are present
bronze1 (*bz1*)	Flavonol 3-O-glucosyltransferase	Bronze/brown aleurone tissues, when all other anthocyanin factors are present
bronze2 (*bz2*)	Glutathione S-transferase	Bronze/brown aleurone tissues, when all other anthocyanin factors are present
colorless2 (*c2*)	Chalcone synthase	colorless aleurone, when all other anthocyanin factors are present
red aleurone (*pr1*)	Flavonoid 3′-Hydroxylase	Red rather than blue pigmented aleurone tissue
salmon silk1 (*sm1*)	4,6-Dehydratase	Salmon colored silks, with *p1* alleles that are functional in silk tissues
salmon silk2 (*sm2*)	Rhamnosyl transferase	Salmon colored silks, with *p1* alleles that are functional in silk tissues
white pollen1 (*whp1*)	Chalcone synthase	White pollen, with recessive *c2*

Table 4 Mutations affecting the flavonoid pathway regulatory genes

Mutation	*Gene product*	*Phenotypic description*
colorless1 (*c1*)	myb-like oncogene	Anthocyanin accumulation in the aleurone tissue
purple plant1 (*pl1*)	myb-like oncogene	Anthocyanin accumulation in vegetative plant parts
pericarp color1 (*p1*)	myb-like oncogene	Phlobaphene accumulation in pericarp and cob tissues, and flavone accumulation in silk tissues
colored plant1 (*b1*)	myc-like oncogene	Anthocyanin accumulation in vegetative plant parts
colored1 (*r1*)	myc-like oncogene	Anthocyanin accumulation in the aleurone tissue, anthers leaf tips, and brace roots
intensifer1 (*in1*)	myc-like oncogene	Intensifies the accumulation of anthocyanins in the aleurone tissue
leaf color1 (*lc1*)	myc-like oncogene	Anthocyanin accumulation in nodes, auricles, leaf blades, and coleoptiles
scutellar node color1 (*sn1*)	myc-like oncogene	Anthocyanin accumulation in pericarps, nodes, leaf blades, silk tissues, and coleoptiles

knotted (*kn*) mutations affect organ/tissue identity (Figure 2j), and the *tassel seed* (*ts*) mutations result in feminization of the tassel (Figure 2g). These types of mutations have been extensively used in the field of developmental genetics to understand the biology of plant development. The dwarf mutations in maize: *anther ear1* (*an1*), *dwarf1* (*d1*), *dwarf2* (*d2*), *dwarf3* (*d3*), *dwarf5* (*d5*), and *dwarf8* (*D8*) have similar distinctive "cabbage-like" phenotypes (Figure 2f). All but *D8* are recessive and respond to exogenous applications of the plant hormone gibberillic acid (GA). The recessive dwarf mutants result from mutations in specific steps in the GA biosynthesis pathway, while the dominant dwarf mutant, *D8*, is the result of a mutation in a GA receptor.

Mutants Affecting Fertilization

The final classes of maize mutations that will be discussed in this article are those that affect fertilization, either through gamete preference or through control of fertility. Several factors influence how readily gametes can successfully fuse to form a zygote. Both megaspores (i.e., female gametes) and microspores (i.e., male gametes) are not very tolerant of chromosomal deletions. However, there are some viable deletions, but they are only transmitted through the megaspore and generally at a lower frequency. Deletions arise through several means, including chromosomal breakage (e.g., ionizing radiation, dicentric bridges), crossing over in inversion heterozygotes, chromosomal nondisjunction, and adjacent segregation in translocation heterozygotes. In addition to deletions, there are genes that influence gamete preference. The gametophyic factor (*ga*) class of mutations affects the functioning of individual pollen grains. For example, *Ga1* pollen grains compete equally with *ga1* pollen grains when the female is homozygous recessive *ga1*. (Remember that pollen grains are haploid.) However, when the female contains at least one *Ga1* allele, $>90\%$ of the fertilizations will involve *Ga1* pollen grains. The *ga1* pollen grains are mostly incompatible when the female possess a *Ga1* allele and in some genetic backgrounds *ga1* pollen grains are completely incompatible.

Recessive mutations have been identified that affect both male and female flower fertility (e.g., *dsy1*, *dsy2*, *pam1*, *pam2*, *as*). Each of these mutations involves defects in various stages of meiosis. Another class of mutations results in male flower sterility (i.e., failure to develop functional pollen grains), but do not affect female flower fertility. This group is collectively referred to as male sterile mutations. Only some of these phenotypes are the result of mutations to a gene that is nuclear encoded. Male sterility in maize can be due solely to mutations in nuclear encoded genes, or it can result from a rearrangement in the mitochondrial genome in a genetic background that is not able to compensate for it with the appropriate nuclear encoded genes. This second type of male sterility is referred to as cytoplasmic male sterility (CMS).

The cytoplasmic genomes, mitochondrial, and plastid, are maternally inherited. That is they are not transmitted through the pollen. Nuclear encoded genes can compensate for the defect caused by the rearrangement in the mitochondrial genome of CMS cytoplasms. These genes, termed *restorer factors* (*rf*), are dominant and restore male fertility in CMS cytoplasm genotypes. In normal (N) cytoplasm genotypes, *rf* genes are not required for male fertility. There are several CMS cytoplasms, however the one that was used quite extensively in commercial North American hybrid seed production fields until the early 1970s was CMS-T. To produce hybrid seed, inbred line parents were either deemed female or male. The male parents carry the dominant *Rf* gene and a normal cytoplasm (N). The female parents need to have two different genotypes. One genotype needs to possess normal cytoplasm (N) and the recessive *rf* gene and

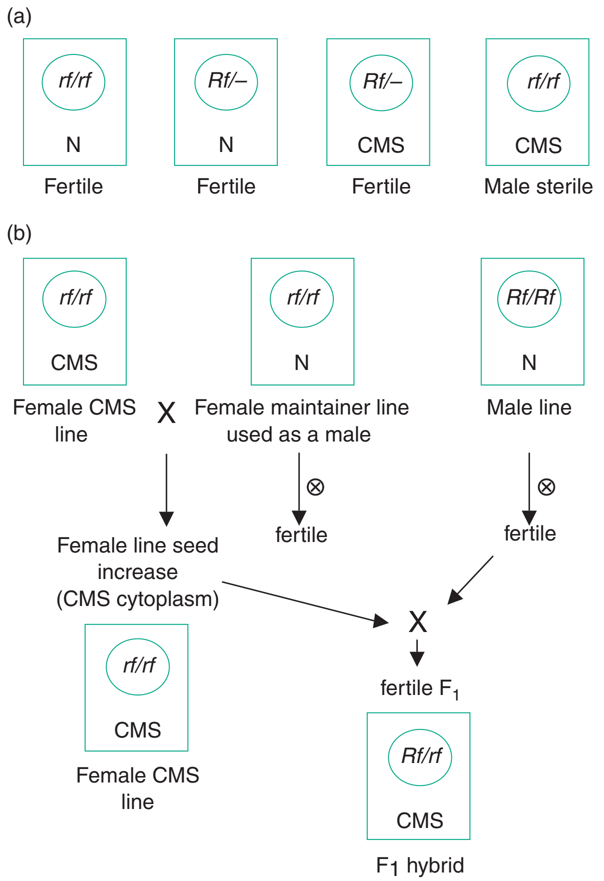

Figure 10 Cytoplasmic male sterility (CMS) and restorer gene (*rf*) system. (a) Four possible combinations of cytoplasms (N – normal vs. CMS – male sterile) and dominant, nuclear encoded restorer genes (*rf*/*rf* – not capable restoring male fertility vs. *Rf*/– – capable of restoring male fertility). (b) System for using CMS to produce hybrid seed. There are two versions of the female inbred, the CMS containing line and the maintainer line. These lines are genetically identical except for the mitochondrial genomes. The maintainer line contains a normal (N) cytoplasm, while the CMS line contains the male sterile cytoplasm. The maintainer line is male fertile, while the CMS is male sterile. The maintainer line is used as a male parent in crosses with the CMS line to produce more CMS seed. The CMS line is used as the female in hybrid seed production fields and the male inbred line is a unrelated inbred line with a different genetic constitution. The male contains a normal cytoplasm and is homozygous for the dominant *Rf* allele. The resulting F_1 hybrid will contain the CMS cytoplasm, but will be heterozygous for the *Rf* gene and thus will be male fertile. Note: ⊗ is genetic's shorthand for self-pollination.

the other genotype possesses the CMS cytoplasm and the recessive *rf* gene. The first genotype is male fertile and is used to maintain both of the female inbred genotypes, while the second genotype is male sterile and is used as the female parent in hybrid seed production fields (Figure 10). Unfortunately, the mitochondrial genome rearrangement that led to male sterility rendered those genotypes susceptible to the fungal leaf disease – northern corn leaf blight (NCLB) (*Exserohilum turcicum*, previously called *Helmithosporium turcicum*). A NCLB epidemic in the US in the early 1970s devastated the maize crop. Use of CMS to produce hybrid seed quickly fell out of favor, and is no longer widely used.

Nuclear encoded male sterile genes (*ms*) are quite numerous, with over 45 unique mutants that confer the *ms* phenotype characterized. Most of the *ms* mutants are recessive, however two dominant *Ms* mutants (e.g., *Ms1*, *Ms2*) have been isolated. The *ms* genes appear to affect all aspects of gamete development from breakdown of early meiotic events (e.g., *ms8*, *ms9*), after meiotic prophase (e.g., *ms17*, *ms23*), during vacuolation of the microspore (e.g., *ms1*, *ms2*), during microspore mitosis (e.g., *ms14*), or after microspore mitosis (e.g., *ms5*, *ms11*). Nuclear encoded *ms* genes have not been used in hybrid seed production, due to the difficulty in generating large quantities of homozygous recessive *ms* female seed.

Maize Genetics Resources

The Maize Genetics Cooperation was formally organized in 1932 by the maize geneticists attending the sixth International Genetics Congress. They agreed to establish a cooperative enterprise to further the advance of maize genetics, specifically by collecting and disseminating unpublished data and information and maintaining and distributing of genetic stocks (e.g., mutants, translocations, etc.). Information was exchanged through the medium of an informal Maize Genetics Cooperation – News Letter (MNL). The newsletter is still compiled and published 71 years later. There are several excellent publicly available resources for maize genetics. For seed of maize mutants and lines containing chromosomal rearrangements, the Maize Genetics Cooperation – Stock Centre, located in Champaign-Urbana, Illinois, USA maintains a collection of over 80 000 pedigreed samples. It is the main repository for maize mutants utilized in research by scientists worldwide. The Stock Centre is located at the University of Illinois and is part of the National Plant Germplasm System and is supported by the US Department of Agriculture, Agricultural Research Service (USDA/ARS). MaizeDB (http://www.agron.missouri.edu/index.html) is a web-based database containing historical and up-to-the-minute information about the maize genome. The database is administered at the University of Missouri-Columbia and is funded through support from the USDA-ARS, National Science Foundation (NSF), and the University of Missouri.

Breeding

E A Lee and L W Kannenberg, University of Guelph, Guelph, ON, Canada

Prior to the introduction of maize hybrids in the early 1930s (US) and 1940s (Canada), maize grain yields were static. Since then average on-farm maize grain yields have risen steadily from prehybrid level of $\sim$1000 kg ha^{-1} to the present level of $\sim$7000 kg ha^{-1} (Figure 1).

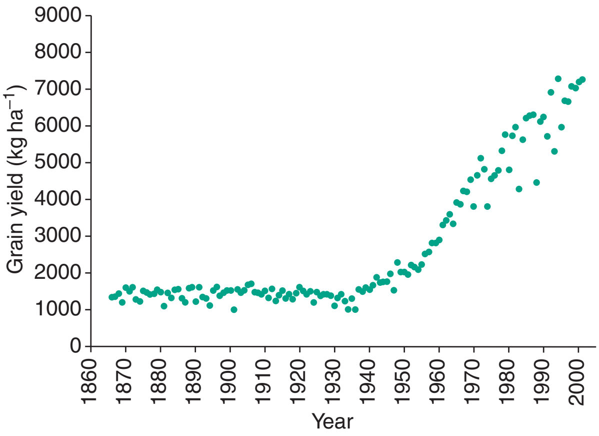

Figure 1 Maize grain yields in US from 1866 to 2001. (Source: USDA, National Agricultural Statistics Service.)

The intent of this brief article is to familiarize the reader with some of the unique aspects of maize breeding, and how these approaches have contributed to the steady increase in North American maize grain yields during the hybrid era. Although the perspective of this chapter will be that of a northern temperate zone, North American breeding program, the underlying concepts are applicable wherever maize is bred.

There are several types of maize grown commercially, each with very different end uses: “number 2 yellow maize,” for animal feed and some industrial uses such as ethanol, corn oil, citric acid, and high fructose corn syrup production, makes up the largest proportion of maize acreage; “sweet corn” for the fresh market, canning and frozen food industries; “popcorn” and “white and yellow food-grade maize” for the snack food industry and general human consumption; “silage maize” and “high oil maize” for animal feed; “waxy maize” for animal feed and industrial specialty starches; and “high amylose maize” for industrial specialty starches. Breeding methods for “number 2 yellow maize” will be discussed in this article; however, methodologies that are applied to specialty types of maize are essentially the same. Whenever possible we have included references to more comprehensive treatments of the topic. Several excellent reviews of the general subject are available, and a recent book (“Specialty Corns”) covers breeding for specific types of maize.

There are two general approaches to maize breeding: pedigree breeding and population improvement. Population improvement has been practiced for centuries by both indigenous peoples and farmers, and, in a more sophisticated form, continues to be used in modern maize breeding; pedigree breeding is a more recent approach that appeared when the potential of heterosis (hybrid vigor) was realized.

Mode of Propagation

Maize is a monoecious plant with separate male (tassel) and female (ear) flowers on the same plant. The tassel produces ~25 million pollen grains while the ear produces ~1000 silks (stigmatic and stylar tissue), each leading to an ovule and a potential seed. Separation of the male and female flowers greatly facilitates controlled crossing. The tassel emerges from the uppermost leaf whorl and primary ear shoots emerge from the leaf sheaths. Once visible the ear shoots are covered, prior to the emergence of the silks, with a glycine bag called a shoot bag. The shoot bag prevents pollen from landing on the silks and unwanted fertilization from occurring. When the tassel is mature, anthers are extruded from the spikelets, followed by dehiscence of the anthers to release the pollen grains. Pollen shed usually lasts for 5–8 days, depending upon the size of the tassel and weather conditions. Peak shedding time is generally mid-day, but is dictated by temperature and humidity. Pollen grains remain viable for no more than 24 h, even under "ideal" conditions. For controlled pollinations, a tassel that is shedding pollen is covered with a brown paper bag called a tassel bag, the day before the pollination is made. The bag is folded securely around the base of the tassel and stapled. The only viable pollen in the bag will be from the tassel. Also the day before the pollination is made, the silks are cut back to the tip of the ear shoot. The next day the tassel bag is removed with the newly released pollen grains in it. The shoot bag is briefly removed from the female plant and the pollen in the bag is sprinkled onto the regrown silks. The shoot bag is replaced, the tassel bag is placed over the shoot bag with the edges wrapped around the stalk and stapled together. Notes regarding the pollination date and the male genotype are written on the tassel bag. Kiesselbach gives an excellent detailed description of the structure and reproduction of a maize plant.

Adaptation

Maize genotypes tend to be adapted to relatively narrow maturity zones compared, for example, to other cereal crops. Ideally, material adapted to temperate zones should flower late enough to produce maximal leaf area to intercept the incident solar radiation, yet early enough that the grain reaches physiological maturity before the first killing frost. Several systems have been developed to aid breeders and producers to place genotypes into the correct adaptation zones. In N. America, the Minnesota relative maturity (RM) system, growing degree days (GDDs), and Ontario corn heat units (OCHUs) are commonly used, while in Europe the Food and Agriculture Organization developed the FAO system (Table 1). Both flowering date and rate of moisture loss from the grain influence maturity; in practice, breeders monitor grain moisture at harvest to assess maturity. Selection for hybrids that can take full advantage of the available growing season in the various maturity zones has resulted in very specific adaptation for a given hybrid.

Table 1 Maize relative maturity rating systems: RM, GDDs, OCHUs, and FAO

Germplasm

The genetic base of North American hybrid maize industry represents only a small portion of the entire *Zea mays* gene pool. There are 250–300 races of maize, of which only one, the Corn Belt Dent, is the predominant source of commercial germplasm. Of the hundreds of open-pollinated varieties of Corn Belt Dent that were grown up to the 1940s, only half a dozen or so can be considered as significant contributors to current inbred lines. But the overwhelming majority of the inbred lines trace their pedigree back to only two open-pollinated varieties, Reid Yellow Dent and Lancaster Surecrop. All North American hybrids have at least one parent from Lancaster or Reid. The great majority of hybrids are, in fact, crosses of a Reid line derivative with a Lancaster line derivative. Virtually all commercial North American hybrids involve six inbred lines or their close relatives: Lancaster-type inbreds C103, Mo17, and Oh43 and Reid-type lines B37, B73, and A632. Further, these lines are used worldwide in maize breeding programs, either directly as a parent or parents of a commercial hybrid or as a component in an inbred

development program. Concern about the narrow genetic base underlying the hybrid corn industry has led to programs designed to diversify breeding germplasm. The program on germplasm enhancement of maize (GEM) (additional information on GEM can be found at www.public.iastate.edu/~usda-gem) represents one of these efforts.

Pedigree Breeding: The Inbred-Hybrid Concept

Hybrid maize traces its roots back to experiments on heterosis and inbreeding conducted by G. H. Shull at Cold Spring Harbor Laboratories in New York and E. M. East at Connecticut State College. They observed that when maize plants were self-pollinated (i.e., inbred) in successive generations, their vigor and grain yield rapidly deteriorated. However, when two inbred lines from unrelated populations were crossed, both vigor and grain yield of the F_1 hybrid often exceeded that observed for the original source populations. It was these observations, made around 1908–09, and methodology outlined by Shull that gave rise to the modern hybrid maize industry. Today most of the maize acreage grown in North America, Europe, and South America is planted to hybrid maize, with an increasing percentage of the acreage in Asia and Africa moving from open-pollinated populations, improved synthetics, and variety crosses to hybrids. There are several types of hybrids (Figure 2). Single-cross hybrids occupy the largest percentage of the acreage in North America. However, double-cross hybrids were grown more widely in the early years of hybrid maize because of seed production problems with the early inbred lines.

This section outlines the primary breeding methodology used to produce inbred line parents for hybrids. In a typical commercial maize breeding company, ~90% of the breeding effort is focused on developing inbred lines and testing them in hybrid combinations using pedigree breeding. Pedigree breeding (Figure 3) starts with a breeding cross (line A × line B), that cross (F_1) is self-pollinated to produce F_2 seed, and individual F_2 plants are selected and self-pollinated to establish individual lines.

Inbreeding via self-pollination continues until the lines are nearly fully homozygous (i.e., F_5 (~94% homozygous) or F_6 (~97% homozygous)). During each generation of inbreeding, visual selection in the breeding nursery is practiced to remove lines that are not favorable. Because the aim of an inbred development program is to create inbred lines that when crossed to unrelated inbred lines will result in superior hybrids, testing of the lines during development must involve crossing them to elite unrelated inbred line testers. In maize, early generation testing is conducted at either F_3 or F_4 to eliminate poor performing genotypes. Early in the hybrid era, breeders observed that grain yields tended to be greater when lines from unrelated genetic backgrounds were crossed, rather than lines from similar genetic backgrounds. This led to the use of heterotic patterns. Several heterotic patterns have arisen during the hybrid era. In northern Europe, the heterotic pattern is typically "flint" crossed to

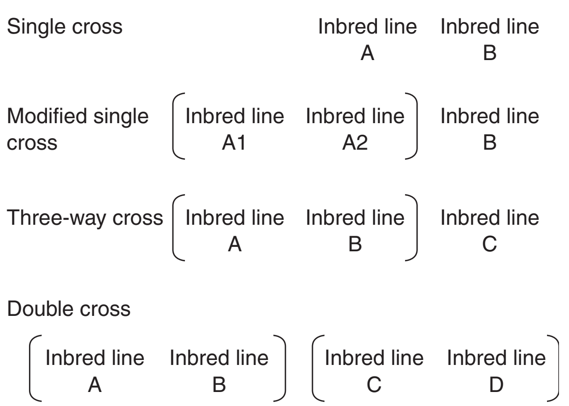

Figure 2 Types of hybrids grown commercially in North America.

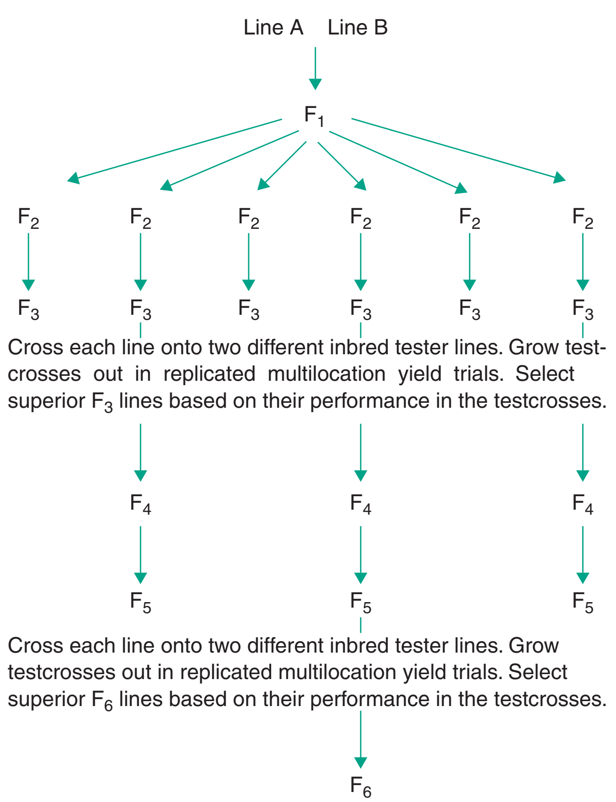

Figure 3 Simplified pedigree breeding scheme, involving a two parent breeding cross.

"dent," with "flint" referring to maize from the Northern Flint race and dent referring to maize from the Corn Belt Dent race. While in North America and southern Europe, the heterotic patterns generally fall within the "dent" category. Patterns such as Iowa Stiff Stalk Synthetic (BSSS), Lancaster Surecrop, and Iodent all trace back to either early synthetic breeding populations or open-pollinated populations. Most commercial companies will have multiple heterotic patterns in which they are actively developing inbred lines, and within a heterotic pattern, there are multiple inbred line families that have been established. For example, within the BSSS heterotic pattern there are at least three inbred line families, B14, B37, and B73, and within the Lancaster heterotic pattern there are at least three inbred line families, C103, Mo17, and Oh43. The hybrid maize industry worldwide is dominated by North American germplasm, but there are specific areas where other backgrounds are grown, e.g., the "orange flints" in Argentina and the "white maize" of southern Africa.

In the early 1980s, commercial maize breeding companies were surveyed regarding their breeding approaches for inbred line development. The information presented below is a synopsis of Bauman's survey. While it is slightly dated, most of the approaches have not changed. The philosophy of the commercial maize breeding industry is twofold: (1) genetic recombination presents opportunities for creating superior genotypes, and (2) evaluation of large numbers of breeding crosses and large numbers of individuals from each breeding cross increases the odds of creating and identifying those superior genotypes. This philosophy results in most maize breeders preferring to avoid breeding strategies that involve backcrossing and instead using strategies that involve creation of new linkage groups, through multiple crosses, and examining large numbers of progenies from each cross. The types of breeding crosses used are narrow-based populations (about six elite parents), elite inbred populations (elite inbred crossed to about six other sources so that 50% of the population is composed of alleles from the elite inbred), double crosses (four inbred parents with equal contribution of alleles), single crosses (two unrelated inbred parents), related line crosses (two related inbred parents), one backcross (two inbred parents, with the F_1 crossed with one of the parents = BC1), and two backcrosses (two inbred parents, with BC1 crossed a second time to the same inbred parent = BC2). Starting with one of these sources, the breeder begins by self-pollinating several plants (S_0 (= F_1) plants) (Table 2).

Once these S_0 plants are self-pollinated, the seed is called S_1 seed, or seed from one generation of self-pollination. Typically 500 S_1 plants will be grown and selected plants will be self-pollinated to establish S_2 families. Considerable visual selection occurs at this stage, with about 180 S_1 plants being selected for further inbreeding. S_2 families are then grown and maintained in what is referred to as ear-to-row, meaning that the S_2 seed from one ear is grown in a single row (20–30 plants) in the breeding nursery. Again considerable visual selection occurs both within an S_2 family and between S_2 families, with about 80 S_2 families being self-pollinated and the "best" ear from each family being selected to advance family to the S_3 generation. As mentioned previously, the aim of an inbred line development program is to produce an inbred line that will result in a high-yielding hybrid. Unfortunately, inbred line grain yield is not indicative of hybrid yield. Therefore, selection for grain yield during inbred line development must be done by crossing the families onto inbred lines from unrelated heterotic groups (i.e., testcrosses). Selection for grain yield in testcrosses can successfully begin in an early generation. Some breeding programs begin this process with S_2 families; however, most programs wait until the S_3 or S_4 generation to begin testcross evaluation. Early testing during inbred development typically involves: (1) using two testers, usually elite inbred lines although occasionally single-cross hybrids are employed, (2) testing at a limited number of locations (~4), usually for only 1 year and with no more than three (and often fewer) replications per location, and (3) current commercial hybrids that are similar in maturity are typically included in the trials as "checks." Only families that in testcross combinations produce hybrids with performance equivalent or superior to the "checks" will be advanced to the next generation. Superior families are selected and the inbreeding and visual selection process continues until the S_5 or S_6 generation, where again the families are evaluated in testcross combinations. Testing at this stage may involve more testers and environments (year and location combinations). Once an inbred line is developed by this process, it will then enter a hybrid development program where it is crossed to numerous

Table 2 Relationship between generation designations F_n and S_n and expected average level of homozygosity from self-fertilization, for all loci at which the F_1 (S_0) was heterozygous

Generation		*Expected homozygosity*

F_5	S_4	93.8
F_6	S_5	96.9

inbred lines and evaluated extensively in an attempt to identify commercial caliber hybrids for sale to farmers.

Population Improvement

Although most of the inbred parents of commercial hybrids have been bred via pedigree selection, some have been selected from populations improved through cyclic recurrent selection. Indeed, some of the families extensively used in pedigree selection originated from inbred lines developed from populations improved through cyclic recurrent selection. Notable examples are the B14, B37, and B73 families, all of which originated from various cycles of recurrent selection in the population BSSS. Cyclic recurrent selection is a procedure whereby several desirable individuals are selected from a genetically diverse population and these individuals, or their progeny, are intermated to generate an improved population (Figure 4).

The procedure is repeated for as many generations as the breeder deems necessary, each generation representing a cycle of selection. The average performance of the population for the traits(s) of selection is expected to improve with each successive cycle of selection as favorable genes for the selected trait(s) accumulate, or, conversely, the frequency of less desirable genes is deceased (Figure 5). Recurrent selection can be effective for many cycles; for example, BSSS was formed in the 1930s and progress remains satisfactory after 15 cycles of recurrent selection.

In breeding programs where hybrids are the product of interest, selections made as parents of the next cycle can be used as well to breed new inbred lines. However, in developing countries where hybrids may not yet be available, the improved population itself may be the product used by farmers. International organizations such as International Maize and Wheat Improvement Center (CIMMYT) and International Institute of Tropical Agriculture (IITA) have been very successful in this endeavor, although they now are also emphasizing the development of hybrids based on inbred lines derived from improved populations.

Cyclic recurrent selection is utilized to improve traits that are controlled by genes at several loci, i.e., quantitative traits. The rate of improvement and duration of effective selection will depend on such factors as initial genetic diversity for the traits, the number of individuals selected as parents in each cycle and their genetic diversity, and heritability, i.e., the proportion of variability due to genetic factors, of the selected traits. Most recurrent selection programs will result in progress for the selected traits, but the desired level of performance can be achieved more rapidly if the initial germ plasm already has segregants with a relatively high level of performance for these traits. For this reason, synthetics formed from elite inbreds often are used to initiate a recurrent selection program. For example, BSSS, the highly productive synthetic from Iowa State University, was formed by intercrossing 16 elite inbred lines with good stalk quality.

Several cyclic recurrent selection procedures have been used to improve population performance (Table 3). For a detailed description of recurrent selection procedures, including expected genetic gain per cycle of selection for the various procedures, the reader is referred to Hallauer and Miranda, 1988. Examples of two recurrent selection procedures, S_2 progeny and half-sib tester, are presented in Table 4. In general, all recurrent selection procedures have given progress for

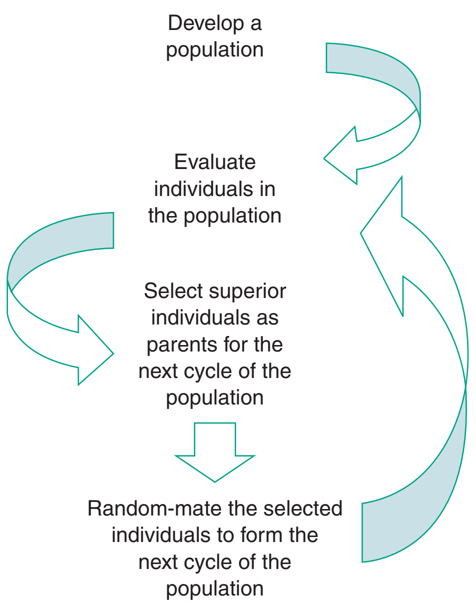

Figure 4 Cyclic steps involved in recurrent selection.

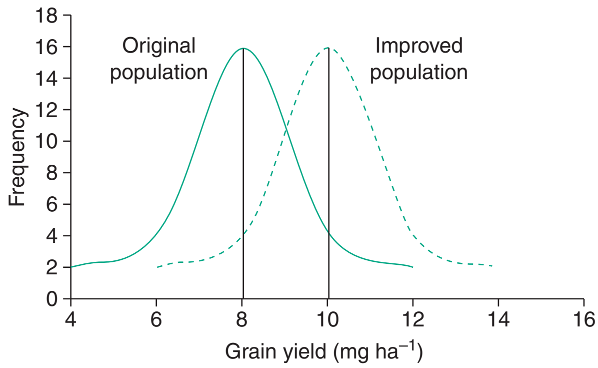

Figure 5 Idealized objective of recurrent selection: improvement of the mean performance of the population while maintaining genetic variation within the population.

the selected trait(s). Several studies have compared some of the procedures, but the results to date are not definitive because of such factors as different germ plasms and their levels of genetic diversity among studies, different procedures being compared in different studies, switches in selection procedures over time, varying number of cycles of selection among the studies, different selection intensities, etc. For example, mass selection might be effective in the early cycles of selection in a population with extensive genetic variability, whereas in later cycles, when genetic variability is reduced, selection methods requiring progeny testing might give greater progress. Selfed progeny selection is expected to be effective because selfing results in deleterious recessive genes being revealed as homozygotes instead of being masked from selection by a dominant gene in the heterozygous state. In contrast, half-sib tester recurrent selection can result in the tester genes masking deleterious genes in the population; however, the tester, especially an elite inbred tester, helps to ensure that lines derived from the population will combine well with elite inbreds to produce a superior hybrid. Visual selection among S_1 lines in the breeding nursery, which is common to both selfed progeny and half-sib tester methods, helps to reduce the frequency of deleterious recessive genes. Also, testcrossing of the selected lines in the inbred development phase of selfed progeny testing helps to enforce the desired combining ability in that procedure.

Some breeding systems for population improvement integrate two or more cyclic recurrent selection

Table 3 Some methods of cyclic recurrent selection for improvement of maize populations

Mass. It is the oldest method of recurrent selection. Individual, open-pollinated plants are selected from populations grown in isolation. Bulked seed from the selected plants are planted in the next cycle. An often-used variation is to impose a grid on the isolation block and then select the best plant within each component of the grid. Grid selection reduces the effect of variable growing conditions in the isolation plot. Mass selection requires one season per cycle and is most effective in populations with high genetic variability for the trait(s) of interest and especially with highly heritable traits.

Ear-to-row. Seeds from selected individuals in a population are planted on an ear-to-row basis, i.e, each row is from seed of one selected plant. The plot is grown in isolation and the plants are open pollinated. The best individuals in the best rows are selected for ear-to-row planting in the next cycle. A common variation is modified ear-to-row selection, whereby the individual ear-to-row plots are detasseled before pollen is shed and male (pollinator) rows from bulked seed of all the entries are planted at regular intervals throughout the isolation block. Undesirable plants in the male rows can be rogued before pollination. In addition, the entries are tested in one or more replicated trials to identify the best performing entries. From the isolation block, the best individuals in the entries selected from the replicated trial data are chosen for the next cycle of modified ear-to-row selection. Each cycle requires one season.

Half-sib family. Individual ear-to-row families are selected based on data from replicated trials at two or more locations. Residual seed of the selected entries is then used for systematic intercrossing of the selections. Thus, unlike mass or ear-to-row recurrent selection, the pollen sources also are only from the selected entries. Individual plants are selected within each family in the intercrossing block for entries in the next cycle. Each cycle requires two seasons, i.e., one year if both summer (for testing) and winter (for intercrossing) facilities are available.

Selfed progeny. Selected plants (S_0) within a population are self-pollinated to produce S_1 lines. The S_1 lines are tested in replicated trials at two or more locations, and residual S_1 seed of the selected entries is planted for intercrossing to produce the next cycle of the population. Three seasons are required per cycle, or two years if a winter nursery is used. An alternative procedure is to plant the S_1 lines in the breeding nursery and perhaps in a pest nursery as well. Visual selection is practiced among the S_1 lines, and selected plants within the selected lines are selfed to produce S_2 seed. S_2 lines are then evaluated in replicated trials. This procedure increases the efficiency of costly replicated trials by eliminating visually undesirable families beforehand. Furthermore, if a winter nursery is used, a second generation of intercrossing of the selected entries can be done, thus enhancing genetic recombination, and therefore genetic variance, before initiating the next cycle of selection. Six seasons are required per cycle, or three years with a winter nursery. **Table 4** presents a season-by-season description of S_2 selfed progeny recurrent selection.

Half-sib tester. The procedure is similar to selfed progeny recurrent selection except that the S_1 (or S_2) lines are topcrossed to a common tester, e.g., a population, a hybrid, or, most frequently, to an elite inbred line. The topcrosses are then evaluated in replicated trials and residual S_1 (or S_2) seed of the selected entries used to plant the intercrossing block. Compared to the selfed progeny procedure, an extra season is required in order to make topcrosses. Thus, four seasons are required if S_1 lines are topcrossed, and seven seasons if S_2 lines are used. However, if a winter nursery is used, a cycle still can be completed in 2 years with S_1 lines and in 3 years with S_2 lines. **Table 4** presents a season-by-season description of half-sib tester recurrent selection using S_2 lines and an inbred tester.

Full-sib. Selected plants in the population are crossed in pairs to produce seed of full-sib progenies. The full-sib progenies are evaluated in replicated trials and the selected full-sib progenies are intercrossed to form a new cycle. Each cycle requires three seasons or 2 years if a winter nursery is used.

Reciprocal recurrent. This procedure is designed to improve the cross-performances of two complementary populations. It is essentially the same as half-sib tester, but the tester for each population is the other population or an inbred line from that population. A full-sib version uses plant-to-plant crosses between the two populations.

Table 4 A season-by-season description of S_2 selfed progeny (S) recurrent selection and half-sib tester (HS) recurrent selection with an elite inbred tester when a winter breeding nursery is available and the breeding program is located in a temperate zone

Winter 1.	For both S and HS: self-pollinate 400–600 selected plants from a population of 1000 or more plants to produce S_1 seed. Select again at harvest.
Summer 1.	For both S and HS: grow out S_1 progeny rows in breeding and pest (if needed) nurseries. Select among S_1 progeny rows and self-pollinate selected S_1 plants within the selected rows to produce S_2 seed. Select again at harvest to give 100 or more S_2 entries for subsequent evaluation.
Winter 2.	No activity in S. For HS: cross the selected S_2 lines to an elite inbred tester.
Summer 2.	(1) For S, evaluate the 100 (or more) S_2 lines in replicated trials at two or more locations. Select 20 or more S_2 lines as parents for the next cycle. The HS program is the same except that testcrosses of the 100S_2 lines are evaluated. (2) Continue selfing and selection among and within the 20 (or more) S_2 lines to produce S_3 seed.
Winter 3.	For both S and HS, use residual seed of S_2 lines selected from evaluation trials for first intercrossing.
Summer 3.	(1) For both S and HS, make a second intercrossing using bulked seed of each line from first intercrossing. This will complete cycle. The next cycle of selection will be initiated in the next winter nursery (as per Winter 1). (2) Keeping only the S_3s, of the best of the 20 (or more) selected lines from the evaluation trials, continue selfing and selecting to produce S_4 seed. Also testcross the S_3 lines to elite inbred testers. Subsequent testcross evaluation trials will determine which lines will continue to be selfed for potential use as an inbred parent in a commercial hybrid.

methods in order to maintain or even enhance genetic variability while shaping this diversity into populations with agronomic/breeding potential. For example, the hierarchical, open-ended, population enrichment (HOPE) system employs three levels of performance to include a highly diverse population at the low-level in which mass selection is used, an intermediate level using selfed progeny recurrent selection, and two elite level populations using full-sib-reciprocal recurrent selection. Introductions are added on a continuing basis and selected entries can be moved upward in the hierarchy. Inbred lines are developed from the elite level populations.

Incorporating GMO Events into Inbred Lines

Since the 1990s, commercial maize hybrids containing transgenic events have been widely grown in North America. These genetically modified organisms (GMOs) involve expression of Bt proteins against European corn borer (*Ostrinia nubilalis*), or resistance to the herbicides – Liberty™ and Round-Up™. For all of these events, only one parent of a single-cross hybrid needs to contain the event, because the events on the market to date are all psuedodominant, i.e., the event has been added to the genome of the GMO parent; therefore, the gene does not have a counterpart on the homologous chromosome segment from the non-GMO parent. To transfer the GMO event from one inbred background to another inbred background, rapid backcrossing is employed. In rapid backcrossing, the GMO parent (donor parent) is crossed to the inbred line of interest (recurrent parent), and then the F_1 is crossed to the recurrent parent (BC1). At this point, the BC1 generation, only 50% of the individuals will contain the GMO event and the average genetic constitution of a BC1 individual is 75% of the recurrent parent's genotype. However, within the BC1 population there are individuals that contain less than 75% of the recurrent parent's genotype and there are individuals that contain considerably more that 75% of the recurrent parent's genotype. Individuals containing the GMO event are identified using an antibody-based assay such as ELISA or spraying with the herbicide. Molecular markers are used to identify the individuals that contain as much of the recurrent parent's genotype as possible. Those individuals that contain the GMO event and a high proportion of the recurrent parent's genome will be backcrossed again to the recurrent parent (BC2) and those BC2 individuals that contain the GMO event again will be identified as well as those individuals that contain >95% of the recurrent parent's genotype. Using this approach and off-season nurseries, breeders can rapidly introduce transgenic events into new inbred lines.

Production of Commercial Hybrid Maize Seed

Hybrid maize seed planted by farmers is produced and sold by commercial seed companies. The production of hybrid seed is an intricate process, because seed quality, seed purity, and cost of production are all critically important factors. Wych provides a detailed description of this process. Most hybrid seed production now is of single crosses (two inbred parents) or modified single crosses (three inbred parents, two of which are closely related), but three-way crosses (three inbred parents) or double crosses (four inbred parents) have been popular in the past (Figure 2). The minimum isolation distance that a seed production field must be from other maize fields is 200 m to ensure purity of the

seed. The typical pattern of planting that is used in a seed production field is 4 : 1, i.e., 4 rows of the female line and 1 row of the male line. This pattern is repeated systematically throughout the field so that a female row is no more than two rows away from a male row.

Plant densities in seed production fields range from 54 000 to 64 000 plants/ha, which is a lower plant density than that normally found in commercial production (~70 000 plants/ha) in North America. The lower plant density is used to achieve maximum yield of saleable kernels. Pollen control in seed production fields is achieved by removing the tassels (detasseling) from the female rows prior to anthesis. Detasseling can be done either by hand or mechanically using cutter bars or pullers. An option to detasseling is to use the cytoplasmic male sterile system with restorer genes. However, this practice fell out of favor in the early 1970s when susceptibility to southern corn leaf blight (*Bipolaris maydis*) was associated with the use of the Texas male sterile cytoplasm (cms-t). Soon after pollination, typically the male parent rows are removed to reduce competition with the female row and the risk of seed contamination at harvest. The female rows will be harvested at ~30–38% grain moisture, i.e., just before they reach physiological maturity. Timely harvest is essential to maintain yield and seed quality. Freezing damage to the kernels and damage due to insects and diseases can reduce the germination percentage of the seed, while delays in harvest will increase the risk of dropped ears. Harvesting is done by machine using mechanical ear pickers. The ears are sorted to remove diseased or undesirable ears and are then dried in low-temperature dryers at temperatures ranging from 35°C to 40°C until the kernels have reached a moisture content of 12–13%. The ears are then shelled, the seed is cleaned to remove foreign material and broken kernels, and the seed is then sized. Sizing involves sorting the seed into lots of uniformly sized kernels. The sized seed is treated with a fungicide or a combination fungicide/insecticide and bagged. Hybrid maize seed is bagged in units either weighing 50 lbs or containing 80 000 kernels.

Summary

The maize breeding methods and philosophy described in this article have been successfully practiced for over 90 years with very little modification to the basic principles: (1) creation of new linkage blocks through recombination; (2) simultaneous evaluation of large numbers of breeding crosses and families within breeding crosses; and (3) progeny testing in testcross combinations using replicated trials in multiple locations. Innovations to maize breeding during those 90 years have involved incorporating new technologies such as mechanical harvesters and planters, computers, electronic data capture devices, and databases. All of these technologies have aided the maize breeder to create and identify superior genotypes more efficiently and thus continue to contribute to the steady grain yield increases in N. America during the hybrid era (Figure 1). Most likely any future technologies, such as genomics, will continue to aid maize breeders to meet this objective, rather than replace the methods and philosophies that have proven to be so successful.

Quality Protein Maize

J S Li, China Agricultural University, Beijing, People's Republic of China
S K Vasal, CIMMYT, Lisboa, Mexico

Introduction

Maize is an important source of protein. Globally, it contributes ~42 million tons (Mt) of protein a year – ~15% of the world annual production of food-crop protein. Therefore, the need to improve maize protein in quality and quantity has been recognized for a long time. Maize protein is mainly stored in both the endosperm and the germ – the two principal parts of maize kernels. But there are large differences in the characteristics of protein present in the two parts. Generally, the germ contains 35% of high-quality protein, whereas the endosperm has only 9% of poor-quality protein. Normally, in maize, the endosperm accounts for 80–85% of the total dry weight of kernels, while the germ constitutes the remaining 15–20%. Hence, ~80% of the total protein content in kernels may be contributed by the endosperm. The relative amounts of protein are also dependent on the type, texture, size of kernels, genotypes, and the environments in which the maize is grown.

According to the solubility in different solvents, maize proteins in kernels are divided into several fractions. The prolamins, referred to as the zeins, are the major protein fraction. They are soluble in alcohol, comprising 52% of kernel nitrogen. The glutelins, which account for 25% of kernel nitrogen, are soluble in dilute alkaline solutions, while the water-soluble albumins comprise 7% of kernel nitrogen. The globulins are soluble in salt solutions and consist of 5% kernel nitrogen. Maize proteins have a low nutritional value because they are deficient in essential amino acids such as lysine and tryptophan. An attempt to improve protein quantity was initiated at the University of Illinois in 1898 with a long term selection. After the 1970s selection, the protein contents in Illinois high-protein (HP) strains reached 26.6%. In contrast, the average contents for proteins in normal maize ranged between 9% and 15%. Unfortunately, the protein yield in Illinois HP strains was not improved in proportion, and the increase in endosperm protein was associated with an increase in the low-quality zeins. Currently, major efforts in most breeding programs are focused on improving the quality of proteins, rather than on developing high-protein maize. This is so especially in developing countries where people depend heavily on maize as a food, and adequate supplies of protein supplements for feed are not produced.

Historical Background

In the 1950s, Mertz's group at Purdue University began research on improving the nutritional value of maize proteins. First, they screened a number of maize germplasm from US corn belt, and Central and South America for low levels of zeins, since they are almost devoid of the two essential amino acids, lysine and tryptophan. None of the varieties screened exhibited a high lysine content. Comparison of Illinois HP (18%) and low protein (LP, 4%) strains at Purdue University by Nelson showed that lysine levels were lower in vitreous high-protein endosperms than in floury, low-protein endosperms. He suggested that "flouriness" might be associated with a high lysine content. He analyzed four floury mutants of endosperm, floury-1, floury-2, opaque-1, and opaque-2. Ultimately, it was found that the opaque-2 endosperm not only contained a high level of lysine, but also a much higher level of tryptophan. After this discovery, similar mutants with high lysine were found in other important cereal crops, such as barley and sorghum.

This remarkable discovery led to an improvement in protein quality using the opaque-2 mutant in maize breeding programs. In the late 1960s, many countries, such as USA, Brazil, China, South Africa, and even the International Maize and Wheat Improvement Center (CIMMYT) initiated breeding programs for developing high-lysine-content hybrids or varieties. The opaque-2 gene (o2) was widely transferred into different inbred lines, and varieties or populations through simple backcrosses. Some high-lysine-content hybrids with o2 were released in USA, China, and South Africa, while some were also developed in CIMMYT. However, some practical problems and limitations of o2 maize became quite obvious when they were gradually applied. A primary failure of o2 maize was the decrease in grain yield. In general, the grain yield of o2 maize hybrids was only 85–92% of the normal hybrids' yield. There was a decrease in kernel weight and density of o2 maize. Also, the kernels of o2 maize were prone to damage by insects and ear and kernel rots were common both in the field and in storage. Its kernels maintained a high moisture level during the development period and tended to dry slower than the normal kernels during the maturity period. In addition, its kernel, which appeared chalky and nontransparent, was not accepted by markets. All these limitations can be attributed to a soft endosperm, which was a characteristic of the standard o2 maize. Therefore, application of the standard o2

maize declined in the 1970s. However, o2 maize is still in use in a few of the adapted areas world over, where the weather is dry and cool.

In order to overcome the defects of o2 maize, many scientists in different countries explored various methods. The major efforts were focused on hardening endosperm textures in o2 maize. Several approaches were suggested, such as recurrent selection and double mutants, using modifier genes. Practically, the third approach may show a great potential. Actually, wide differences in endosperm textures in o2 genotypes were observed when the o2 gene was backcrossed into a series of maize inbred lines. With regard to endosperm structure, some are completely soft, whereas others are partially hard, which is caused by modified genes for o2 locus. Scientists in CIMMYT have developed tropical and subtropical hard-endosperm germplasm combining o2 gene with modified genes during extensive and sustained breeding efforts. They called their hard-endosperm o2 germplasm as quality protein maize (QPM) so that it is distinguished from soft-endosperm o2, which is called as standard o2. The kernels of QPM are almost similar to those of normal maize, but they are homozygous for the o2 allele. Yield improvement, observed in some QPM populations released by CIMMYT, is related to hard or semihard endosperm. The moisture contents and dry-down time of these QPM populations resemble those in normal maize. Ear rot in QPM is also substantially reduced. Recently, germplasm has been used as an essential resource for developing QPM hybrids.

Genetic and Biochemical Basis

The inheritance of o2 gene follows a typical Mendelian pattern, located on chromosome 7 in the maize genome. It is a recessive mutant and its expression requires the homozygous genotype, i.e., o2/o2. The genetic segregation for the phenotype can be observed on a single F2 ear with a ratio of 3 (normal) to 1 (opaque). The o2 gene was initially cloned by Schmist *et al.* and later by Motto *et al.* in the 1980s. More recently, its molecular mechanism has been described. The o2, as a dominant gene, encodes a DNA-binding protein belonging to the basic leucine zipper class, which is involved in the transcription of zein proteins. This protein can bind the 5′ flanking sequences of the genes encoding the 22 kDa α-zeins and serve as a transcriptional activator during the transcription. When O2 mutates into o2, the transcription of α-zeins is significantly reduced, resulting in a remarkable alteration in the amino acid content. But amino acids are not completely eliminated in o2/o2 mutants, since o2 is only one of the transcription factors involved in the expression of α-zein genes. The increase in the lysine and tryptophan contents results from the decreasing quantities of zein protein.

Traditionally, maize zein proteins were classified by molecular weights. A new classifying method is proposed based on their primary genes and amino acid sequences when many genes of storage proteins were found. According to this method, they are divided into four groups, α-zein (22 and 19 kDa), β-zein (14 kDa), γ-zein (27 and 16 kDa), and δ-zein (10 kDa). The α-zein protein group is the largest among them, consisting of ~80% of the total proteins. The maize zeins are synthesized by membrane-bound polyribosomes, and then are moved to the lumen of the endospermic reticulum, where they are assembled into insoluble protein bodies. There are obvious differences in the composition and size of protein bodies between the aleurone and endosperm of kernels. The small protein bodies containing β- and γ-zeins exist in the subaleurone, whereas the large protein bodies are found in endosperms, containing α-, β-, and γ-zeins. The quality of proteins in the o2/o2 genotype is improved with the decrease of α-zeins, which contain no lysine. For the same reason, the sizes of protein bodies in the endosperm of o2/o2 are significantly smaller than those in normal endosperms (Figures 1c and 1d). As a result, the endosperms of kernels turn into being nontransparent and soft.

Modifying genes played an important role in converting soft endosperms of standard o2 maize into hard endosperms of QPM. These may be defined as a series of genes, which, on their own, could not have any effect when o2 gene dose did not exist, but they modify kernel phenotypes of the o2/o2 when it is homologous. Generally, inheritance of modifying genes expresses the quantitative nature of this effect. In a segregation generation, there is a normal distribution for endosperm texture, varying from soft to hard. Some researches indicate that the additive effects of modifying genes seem to be more important in controlling kernel vitreosity for o2 maize in this genetic system. Others suggest that there may be significant effects on kernel vitreosity for modifying genes. Extensive studies at CIMMYT demonstrate that there are a number of o2 modifying genes and that several different types of genetic variations are likely to exist in maize germplasm.

In QPM, the biochemical effects of modifying genes tend to increase zein proteins, but high-quality proteins could maintain nominal changes. There are relatively minor differences between o2 and QPM protein in staining density and morphology (Figures 1d and 1f). The protein bodies in QPM have multiple, nonconcentric areas and a large number of dark-stain regions, which are rich in γ-zeins. In addition, the

studies by Larkins's group on immunocytochemistry reveal that the most significant change in QPM endosperm is the increased synthesis of γ-zeins. This increase could result in a higher concentration of protein in endosperm cells, so that there is less airspace in the endosperm, resulting in a hard and translucent phenotype.

Since the endosperm comprises triploid genotypes, dosage effects of modifying genes are observed through analysis of F1 hybrids from reciprocal crosses between modified and unmodified o2 parents. As can be seen in Figure 2, the parent lines and their reciprocal crosses perform a phenotypic gradient toward the types of increasing vitreousness. The xenia effects of modifying genes are also observed in the hardness of endosperm.

Nutritional and Process Values

Repeated experiments on infants, children, adults, and various animals have demonstrated that the nutritional value of o2 maize is superior to that of normal maize. Recently, increasing evidence has indicated that the nutritional values are still maintained in QPM when the limitations of o2 are obviously improved upon. As can be seen in Table 1, the volumetric weight and density in QPM are similar to those in normal grains. Protein, lysine, and tryptophan contents are significantly higher for QPM than normal maize, whereas QPM and o2 maize have the same contents. On an average, QPM has ~40% more lysine and tryptophan than normal maize.

Based on the evaluation of digestibility and nitrogen balance for infant feed, nitrogen-retained intakes from

Table 1 Comparisons of nutrition among QPM, normal, and o2 maize

Item	*QPM*	*Normal*	*Standard o2*
Test weight (kg hl^{-1})	0.79	0.75	0.71
Density (g cm^{-3})	1.31	1.25	1.18

QPM and normal maize in children are 32% and 22%, respectively, indicating a higher efficacy of nitrogen utilization for infant food with QPM. In the animal growth trials, pigs fed the QPM diets consumed 1.97 kg of feed daily and gained 0.75 kg per day, whereas pigs fed normal maize diets, which contain the same level of soybean meal supplementation, consumed 1.86 kg of feed and gained 0.63 kg daily. Other experiments indicated that milk productions of dairy cattle increased when QPM was used as silage.

The wet-milling and dry-milling properties of QPM were also evaluated in order to enhance its utilization in industry. Maize protein is the major by-product of the wet-milling industry, which is used entirely in animal feed. Lysine contents of maize protein for QPM reached 3.06 g per 100 g protein, which is significantly higher than that for normal maize (2.43 g per 100 g protein). Maize protein with a high lysine content can be beneficial in diet formulation for animals since it is an appropriate substitute for the expensive protein supplements. In wet-milling process, starch in QPM endosperm may be easily released from protein matrix since it produces a lower-bound yield, namely, 1.1 g per 100 g protein. On the other hand, there is no significant difference between QPM and normal maize in the physico-chemical properties of starch and in the characteristics of maize oil for wet-milling process. In the dry-milling experiments, the total yield of grits and other products from QPM, such as low-fat meal and low-fat flour, are comparable to those from normal maize. But dry milling of QPM may provide products with improved nutritional value.

Genetic Improvement

The purpose of genetic improvement of QPM is to develop hybrids or cultivars combining o2 gene with the modifying genes, which has not only a higher lysine content but also semihard or hard endosperm. In order to reach this goal, it is very important for breeders to have adaptable germplasm containing modifying genes. The kernel modifications controlled by modifying genes can be divided into two patterns, regular and irregular. In the regular pattern, the hard fraction of endosperm increases progressively from the crown towards the base of the kernels. But in the irregular pattern, the translucent fractions may be distributed among the whole kernel as a band, scattered, resembling a bridge, or vitreous base. Regular modification is more important for genetic improvement of QPM because it is more stable.

Practically, recurrent selection is the most useful breeding method for the development of QPM germplasm. The first stage for QPM improvement is to screen the modifying genes from different resources and develop QPM donor stocks. Extensive studies at CIMMYT indicate that several o2 populations may have a higher frequency of modifying genes, especially in flint varieties from Caribbean Sea and South America. In general, there are two principal ways to develop QPM donor stocks. Intrapopulation selection is used when resources express a considerably higher frequency of modified o2 ears. The other way is to combine partially modified o2 families from different genetic backgrounds into one donor stock. The QPM donor stocks can be used as the basic populations for recurrent selection. A full-sib selection for several cycles is often employed to accumulate modifying genes. First, full-sib families are evaluated for kernel phenotypes among different testing sites. Then, top 10–20 family lines with more vitreous endosperm are chosen and are recombined into the next cycle. Another more efficient but quite complicated approach is backcross-cum-recurrent selection program, since QPM is involved in two genetic systems, the o2 gene and modifying genes. The procedure includes backcrossing o2 gene into modified family lines and accumulating modifying genes within modified family lines. In addition, other traits are also selected in this program. A series of improved QPM populations have been released by CIMMYT.

Recently, the development of QPM hybrid has been given more attention all over the world because hybrids exhibit more advantages than improved populations, such as higher yield performance and more uniform and stable traits. The breeding procedure for QPM hybrids includes three basic steps. The development of elite QPM inbred lines is the vital step. They could be bred with QPM germplasm as in conventional breeding. Then, the combining abilities of QPM inbred lines are measured and superior combinations are selected for adapted planting areas. Finally, QPM hybrids are released into commercial production.

During developing QPM inbred lines, analysis for protein quality is essential because vitreousness in endosperm may have a negative relationship with protein quality. In order to maintain high lysine contents, endosperm analysis is preferred since the modification in QPM only involves changes in endosperm.

Future Prospects

More recently, molecular marker technique has provided a powerful tool to facilitate breeding practices. In QPM breeding, sequence tagged site (STS) markers for o2 gene could be designed on the basis of its sequence. With this molecular marker, o2/o2 genotypes could be precisely selected at any stage even though hard endosperm QPM is very similar to

normal endosperm. Another application for molecular marker technique in QPM breeding is to map modifying genes. Molecular markers will allow the screening of whole maize genome to identify the modifying gene loci. These molecular markers linked with modifying genes could be employed to conduct marker-assisted selection (MAS) for modifying genes. In addition, with the development of functional genome, further investigation will reveal modifying gene function and improve the understanding of the biosynthesis of γ-zeins in QPM endosperm. These processes could offer the potential to improve QPM by genetic engineering.

There is increasing interest in QPM developments in the developing world, where QPM has performed well. The development of QPM hybrids has especially enhanced heterosis utilization, which could raise QPM yield and improve its tolerances to stress significantly. There is no doubt that QPM will make great progress in the near future.

Dry Milling

S R Eckhoff, University of Illinois, Urbana, IL, USA

Introduction

Dry milling is often used to describe three different processes when talking of maize. The first process, stone grinding, is the oldest and is also known as whole kernel dry milling or full fat dry milling. Whole kernel dry milling does not seek to fractionate the maize kernel but to grind it into uniform size particles, usually flour or meal. The term “stone ground” refers to the use of two stone grind plates between which the maize is ground into a flour or meal. Other devices for particle size reduction can be used to produce this meal or flour, including hammer mills, pin mills, and disk mills. The defining characteristics of this type of dry milling is that nothing is separated in the process and the resultant product is used for human nutrition. The products are usually referred to as “full fat” flour or “full fat” meal because the germ has been left unseparated from the other components. Full fat products have a fuller flavor but a much shorter shelf life than degermed products due to the potential for rancidity of the oil.

The second process refers to the production of ethanol from maize. A hammer mill is used to grind maize to the desired particle size prior to jet cooking, liquefaction, saccharification, and fermentation. Recently, this process is being referred to by the name “Dry Grind Ethanol” in order to prevent confusion.

The third process referred to as maize dry milling is the process we are considering in this article. More accurately referred to as degerminated dry milling, this process attempts to remove the germ and coarse fiber (or pericarp) from the collection of grits, meal, and flour that is left. Degermination improves the shelf life of the endosperm products by removing the bulk of the oil in the maize kernel (~75%). For information

on the structure and composition of maize kernels, *see* **Maize**: Wet Milling.

Process Overview

Maize, which has been mechanically cleaned to remove broken pieces of maize, weed seed, other grains, and any other adulterant, is tempered. Numerous tempering methods exist, but a single stage tempering would be to first spray 6–8% water on the kernels as they are dropped into a low rpm horizontal screw conveyor or similar type of mixing device. Residence time in this screw conveyor would be 2–10 min. The surface wet maize is then dropped into the top of a tall, small-diameter mass flow bin, which feeds the degerminator (Figure 1) for a total tempering time of 15–40 min.

The degerminator is fed at a constant rate and results in one or two streams containing a mixture of detached germ, pericarp pieces, and endosperm pieces of varying sizes. In degerminators with two streams, the objective is to get the germ and pericarp to go in one stream with small endosperm pieces ("thru stock") and to get large endosperm pieces ("tail stock") to go in the other.

Exploiting the density, size, and aerodynamic differences that exist in the different particles, it is possible to make a separation between pericarp pieces, germ, and endosperm and to separate out different size fractions of endosperm. To accomplish these tasks, a variety of equipment can be utilized including most of the equipments described in **Wheat**: Dry Milling. Because of the differences in objectives, maize dry millers generally do not find it cost-effective to use equipments other than sieves, aspirators, roller mills, and gravity tables. Sieves, aspirators, and roller mills are almost essential components of a maize dry mill but good germ separation can be achieved without using gravity tables as shown in Figure 1. The figure shows the process flow for a simple, low-cost dry mill using a Beall-type degerminator. The initial and maintenance cost of gravity tables make recovery of the germ using a roller mill and sieve attractive. However, worldwide there are many maize dry mills still using gravity tables to separate out germ.

In Figure 1, the tempered maize is split into two fractions by the degerminator. The first fraction (40–80%) is the "thrus" referring to germ, endosperm, and pericarp fiber that passes through the

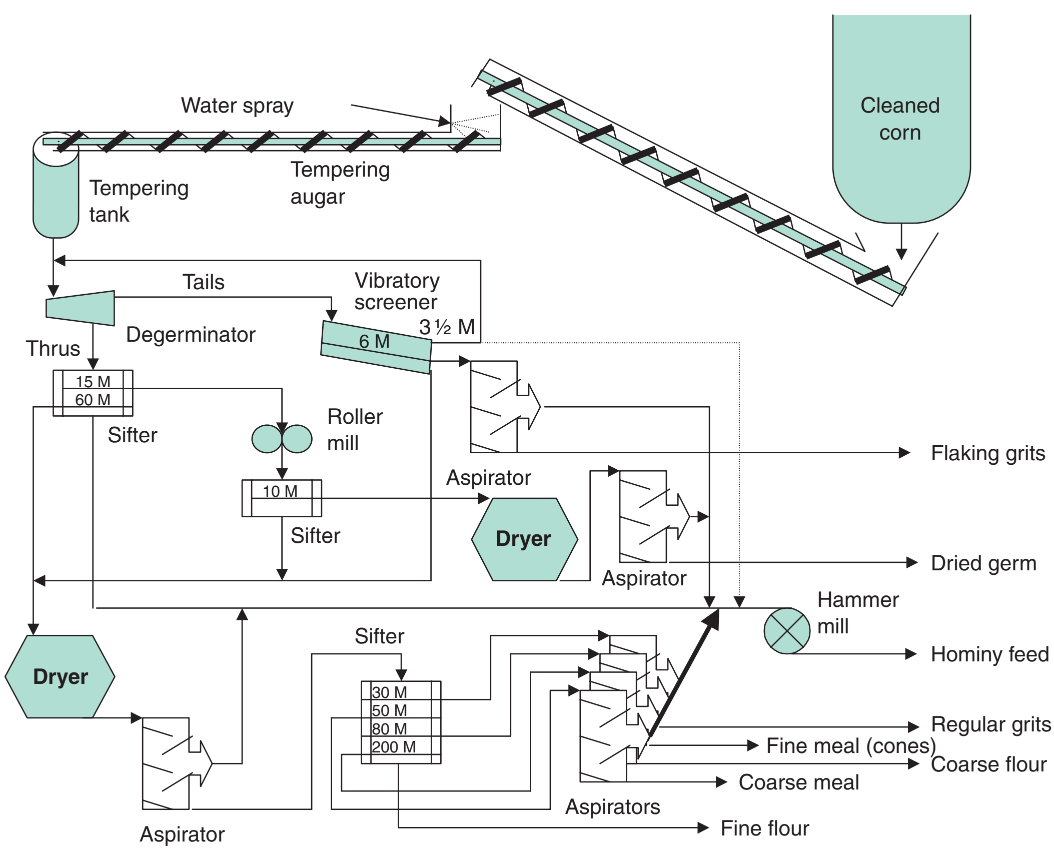

Figure 1 Process flow diagram for simple maize dry mill.

screen on the degerminator. The second fraction, the tails, is usually smaller (20–60%) and is a function of maize quality and genetics. The tails, being predominately flaking grits, some recycle and flour, can be screened with a vibratory screener using a 5.6 mm screen as a scalper to recover oversized grits with attached germ and unbroken kernels. This scalped material can be recycled or disposed into the hominy feed fraction. The vibratory screener also has a 3.55 mm screen for recovery of flaking grits (−5.6 mm + 3.55 mm; this designation means "through a 5.6 mm screen and on a 3.55 mm screen). The material which goes through the 3.55 mm screen is mixed with the −1.25 mm + 250 μm fraction sieved from the thrus. The flaking grits are then aspirated, with the aspirate going to the hominy feed fraction. A stationary sieve (as shown in Figure 2) can be used in place of the vibratory screener with comparable results. The stationary sieve can often be built locally for lower cost and operates with no energy input and minimal maintenance.

Screening devices come in many configurations and sizes but employ the same basic principle for achieving separation, size difference. Particles smaller than the screen opening can fall through, while those larger than the screen opening remain on the screen. The probability that any piece of maize material will pass through the screen is not just a function of screen opening size but is also affected by the length of exposure the piece of maize has to the screen opening. Three major factors affect the length of exposure: (1) the depth of the material on the screen, (2) the distance the particles must transverse (basically the length of the screen), and (3) the amount of angle at which the screen is operated. Most screens used in corn dry milling are metal wire screens with the size openings given in millimeters or micrometers.

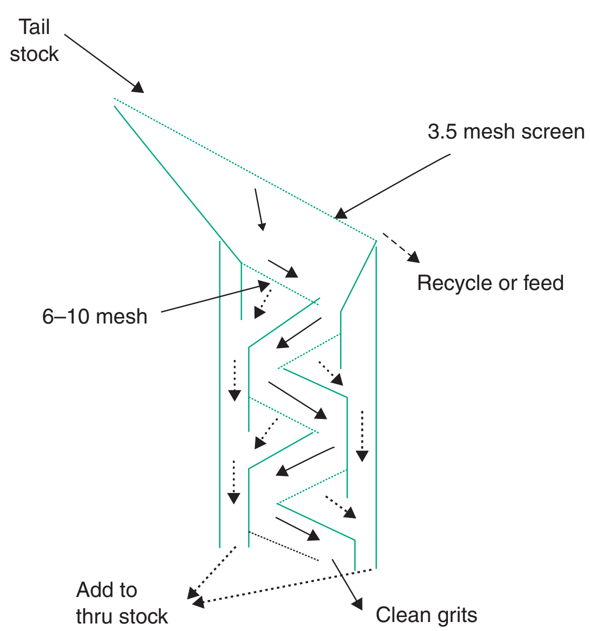

Figure 2 Static sifter.

Most commercial screens enhance the separation process by using some type of mechanical action. There are a variety of reciprocating actions, that are used to help the material to be removed, work its way to the screen surface. The action also serves to increase the exposure of the maize material to the screen openings, since the particles are agitated or turned to expose different orientations to the screen openings. This increases the likelihood of the particle falling through the screen.

Although it is often said that aspiration will separate light or less dense material, material with a density or weight greater than the maize fraction may actually be removed using aspiration because the aerodynamic characteristics of a particle depends upon shape, texture, and weight or density and not just density or weight alone. There are two primary forces which act upon a particle in an air stream. The downward gravitational force experienced by the particle is due to its total weight (total mass multiplied by the gravitational constant) and not due to its density. The force which counteracts the gravitational forces is the upward drag force. It is made up of two components: form drag and frictional drag. The amount of frictional drag is dependent upon surface texture and total exposed surface area. Form drag, which is dependent upon the projected area of a particle and upon its shape characteristics, dictates the amount of separation that will occur in an aspirator.

The rate at which a particle will move up or down in an air stream depends upon the difference between the drag force and the gravitational force. If the two forces are equal, the particle will remain stationary. If the drag force is greater than the gravitational force, the particle will be carried upwards by the air stream.

Aspirators are designed to force an air stream across the path of flowing mill products, usually at a 90° angle to the flow. The less aerodynamic fiber particles are the first to be removed by aspiration. The small, soft, floury endosperm pieces are usually the next particle group to be removed. Larger/heavier particles can also be removed, if enough aeration is used in the system for them to reach incipit fluidization. Multiple pass aspirators, where the flowing particle stream is exposed sequentially to multiple air streams, are generally preferable to a single air stream aspirator.

The thrus fraction from the degerminator is sieved into three fractions, a +1.25 mm, −1.25 mm + 250 μm, and −250 μm. The +1.25 mm fraction contains large grits and grits with attached germ or

pericarp and germ. This fraction is passed through a roll stand with a gap setting which breaks the large (−3.55 mm + 2 mm) grits and grits with attached germ or pericarp. The germs, containing ample water, do not break but rather are squeezed or compressed into flat flakes. The germ can now be sieved out of the endosperm material, dried, and aspirated to recover any pericarp and small endosperm material. The aspirate is added to the hominy feed. The germ can be pressed on-sight, recovering ~14–21 kg oil per MT or delivered to solvent extraction facilities where approximate recovery of oil can vary from 21 to 23.6 kg oil per MT.

The bulk of the thru material (−1.25 mm + 250 μm) is dried, aspirated, sieved into various fractions, and reaspirated to achieve a variety of low fat endosperm products. If necessary in order to achieve mill balance, larger grits and flaking grits can be reduced in size by roller milling to achieve a more marketable granulation. The −250 μm fraction is known as degerminator fines or degerminator flour and is usually added to the hominy feed due to its high fat content.

A roller mill consists of a pair of parallel cylindrical rolls made out of hardened steel, which rotate opposite to each other, rotating so as to pull material into the nip between the two rolls. The rolls generally range in size from 10 to 40 cm (diameter) and up to 1.3 m in length. The roll faces can be corrugated with a variety of cuts or can be smooth face; however, smooth face rolls are generally not used in maize milling. The gap setting between the two rolls is adjustable and the rolls are operated with a slight rpm differential. The larger the particle size being roller milled, generally the fewer the corrugations per cm on the roll face. As the particle size decreases, the corrugations per cm increase.

Tempering

Tempering maize is much different than tempering wheat and other cereal grains milled into flour. The purpose of tempering wheat is to induce a moisture gradient in the kernels that causes the endosperm to stress crack and the bran layer to release from the endosperm. Wheat is often tempered overnight to allow the added moisture to distribute uniformly throughout the kernel and then 10–30 min before processing the wheat, it is tempered an additional 4–6% moisture to enhance germ and bran layer recovery. The moisture added in the overnight temper is beneficial to keep the flour particles from becoming too dry due to pneumatic handling and the heat from the break and sizing rolls. The stress cracking lowers the energy required to produce flour and helps insure that it will be easier to separate from the bran.

In maize dry milling, tempering is done to create differential swelling resulting from the germ and pericarp of the maize absorbing moisture and swelling faster than the endosperm. This swelling loosens the connecting tissue between the pericarp and the aleurone layer of the endosperm and between the germ and the endosperm. In tempering maize, the objective is to not increase the moisture content of the endosperm. Increasing the moisture of the endosperm risks the chance of creating stress cracks, which will lower the yield of large grit material, and means that the moisture absorbed by the endosperm must be removed by drying, thereby requiring more capital and energy. In scientific literature, maize tempering is usually shown as a two- or three-stage process. Industrial practice in the USA for the last 40+ years has been to use a single-stage temper (6–8%, wb; 10–40 min). For very dry maize (<10% moisture, wb) single stage tempering is still used. It is preferable to buy maize at 12–4.5% moisture content than to use such low moisture maize.

Steam or hot water can be used to increase the rate of absorption and decrease temper times, especially in cold weather climates. Steam alone can be difficult to control without overheating the kernel surface and gelatinizing starch. A combination of steam and hot water is recommended in such cases.

Types of Degerminators

There are many "brands" of degerminators used around the world with the majority of them being emulations or modifications of a few basic designs. With some exceptions, the patents on most commercially used degerminators have expired and reverse engineering has become an accepted practice in the industry. For example, the patent for the Beall degerminator was granted in 1901 and it is not uncommon to see similar degerminators for sale by competing major manufactures. Parts are sometimes interchangeable although they may not be of the same quality. This reverse engineering keeps prices for degerminators competitive and makes it difficult for new degerminators with slightly improved performance to enter the market. The various degerminators in use can be classified into six categories.

Kernel to Kernel Shear (Beall Type)

The Beall degerminator is one of the oldest maize degerminators but is still recognized as the best when the objective is to produce low-fat flaking grits (−5.6 mm+3.55 mm). The design for the Beall has been widely copied and is one of the most used degerminators worldwide (Figure 3).

The basic Beall design is a truncated cone covered with hemispherical nodules, known as "pearling

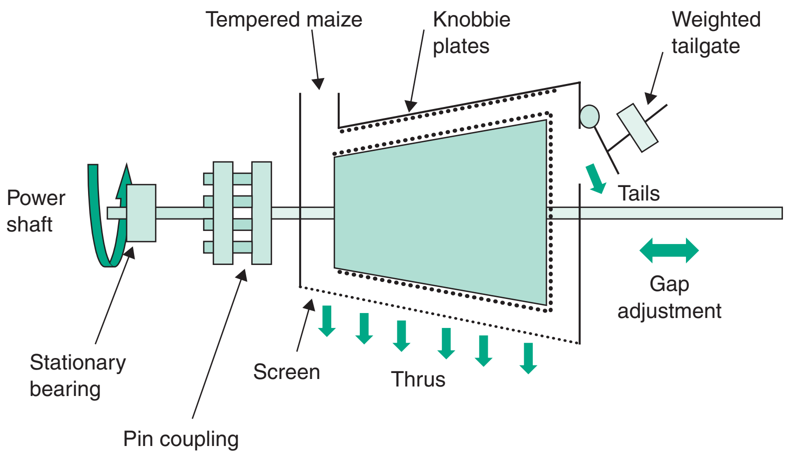

Figure 3 Diagram of a Beall-type degerminator.

knobs" or "knobbies," of ~2.5 cm in diameter, inside an outer truncated cone, half of which is screen surface, and the other half knobby surface. The inner cone is driven counter clockwise and can be moved in and out, relative to the outer cone as a means of controlling gap spacing between the two cones. Tempered maize is fed into the degerminator at the top of the small end of the cone (Figure 3). Spiral ridges on the small one-third of the cone (not shown) moves the kernels away from the opening and helps fill the cavity between the inner cone and the screens. Discharge from the degerminator occurs when the kernel breaks into pieces. The smaller pieces work their way to and then go through the screen, while the large flaking grits and unbroken kernels are shoved out the tailgate. The thrus consist of whole and broken germ pieces, pericarp and smaller endosperm pieces. A 6.4 mm round hole screen is common but different size screens can be used depending upon the size of the maize kernels and the separations desired.

At a steady state, the degerminator is half to two-thirds full and the knobbies on the surface of the rotating cone create shearing action between adjacent layers of kernels. It is this kernel-to-kernel shear which breaks open the kernel and releases the germ. Because the knobbies are rounded, there is no significant direct impact forces exerted on the kernels by the degerminator. Once the kernel is broken, the germ and pericarp are released due to continued shearing action. Eventually the broken particles reach the screen surface where all but the largest grits can easily be discharged. A high percentage of the thru material passes through the first two-thirds of the screen surface. If the tempering time was too short or too much water was added, the pericarp can become gummy and clog up the screen. Very quickly the whole degerminator will plug and the drive belts will slip or the direct drive shear pins will break. The degerminator must then be disassembled and cleaned. The last one-third of the screen surface and the tail area (between the large-diameter end plate of rotor and tail plate surface) is a polishing area where the large grits are abrading each other, removing loose, soft endosperm material, attached germ and pericarp, and breaking down weak grits. This polishing action can be enhanced by increasing the tailgate weight distance, thereby increasing back-pressure.

Increasing the gap increases residence time and results in increased capacity and cleaner flaking grits. While the manufacturer sells the Beall with half the outer cone as knobbie plates and the other half as screen, many dry millers operate with three-fourth screen and one-fourth knobbie plates. This setup has increased capacity and some reduction in performance.

Impact

This category includes a variety of horizontal and vertical disk pin type mills. Vertical disks with concentric rings of intermeshing pins with one or both of the disks driven are classically known as pin mills. If both disks are rotating, then they spin in opposite directions. The maize is fed into the center of the disks and pass between the rotating pins, where they are randomly impacted. The number of impacts is generally high and the magnitude and frequency of impact does not give good pericarp and germ separation from the endosperm as much as simply grinding the maize.

One type of pin mill is an Entoleter, which comprises two horizontal disks with two rows of pins on the rotating bottom disk and one row of intermeshing pins on the stationary upper disk. The maize is dropped into the center of the bottom disk (Figure 4), where it is accelerated by centrifugal force toward the rotating pins. The maize must pass between the

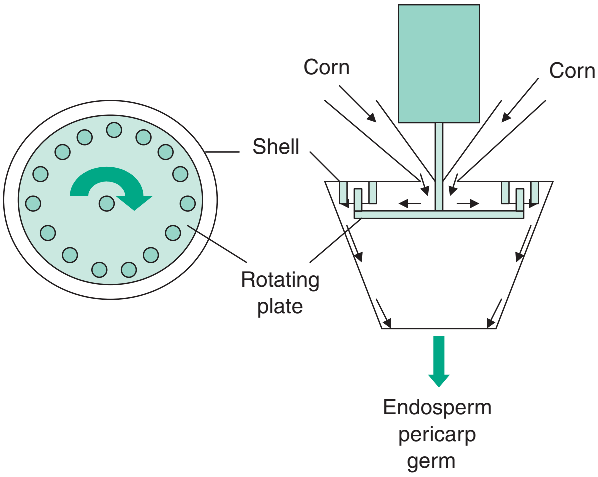

Figure 4 Diagram of the Entoleter degerminator.

three rows of pins before being collected. Because there is a limited number of impacts, the Entoleter recovers more whole germ and produces a larger germ fraction with equivalent oil content than the Beall. However, it produces more mid-size grits (-4 mm $+2$ mm) and less flaking grits.

Multiple Impact/Shear

This is probably the most common type of degerminators worldwide (Figure 5). Tempered or untempered maize is fed into the annular region between two horizontal or vertical cylinders or near cylinders (with flat surfaces to connect impact attachments). The maize transverses the distance of the cylinder being impacted by the attachments to the inner cylinder. The impacting creates a shearing effect between the kernels as in the Beall degerminator. Small particles pass through the screen and large particles drop over a wire at the end of the cylinder. The attachments vary over a wide range of types, shapes or angles but all provide some degree of impact. Some models separate the flow through the screen into two or more sections and there are a wide variety of outlets. The screens can be made adjustable to increase or decrease the gap and some of the outer cylinder peripherals may be solid with or without rasp bars or other attachments to increase shear. The disadvantages of such machines, compared to the Beall, are that the impacts sustained by the kernels result in a reduction of flaking grits and the machines have reduced flexibility for making adjustments in gap and tailgate backpressure. These machines are acceptable and even preferable when producing prime products other than flaking grits because of higher prime product yields.

Compression (Cereal Technologies Inc.)

A series of patents by Jim Giguere and owned by Cereal Enterprises, Inc. (now Cereal Technologies Inc.) describes mechanisms by which individual kernels are oriented and compressed lengthwise resulting in whole germ separation from the endosperm. The patents describe the mode of action but the actual design of the degerminator is guarded. Several plants in the US have been built using this proprietary technology. The process provides efficient clean germ recovery and high recovery of endosperm, primarily as brewers grit size material or smaller. Good separation has been found using tempered and untempered maize. Process yields are reported to be less sensitive to maize quality or hybrid type than other degerminators.

Roller Milling

A series of roller mills, each followed by sifting and aspiration, can be used to recover a germ fraction from maize. A well-adjusted coarse break mill can crack the kernel, compress the germ so that it pops out and release the pericarp. Subsequent rolls and other mill separation equipment can be used to “clean up” the fractions. The use of roller mills for degermination is common in Africa, where two to three small roller mills with different corrugations can accomplish degermination and all needed particle size reduction.

The advantage of using a roller mill to degerminate maize is the availability and low cost of the roller mill since it is used in all types of dry milling (wheat, oats, etc.). There are several disadvantages of using a roller mill to degerminate. First, the system is not capable of producing large flaking grits. Second, the separation of germ and pericarp is not as clean as with other degerminators. Third, the roller mill has an adjustable fixed gap so the efficiency of degermination is a function of the range or spread of kernel size in the sample being tested. If the mill is adjusted to crack the smallest kernels, the larger kernel’s germ is often damaged. If the mill is adjusted to optimally handle large kernels, a lot of smaller kernels will pass through unaffected. A series of break rolls can be utilized to handle the different size kernels or the maize can be presized and the mill adjusted for each size fraction. However, considering the requisite aspirators and sifters, any economic advantage over a dedicated degerminator is quickly lost as the system becomes more complicated.

Products and Uses

The products produced from dry milling can be simply classified as grits, meal, flour, germ, and hominy feed. The germ fraction (~20% oil) is usually pressed to recover oil that commands a premium over

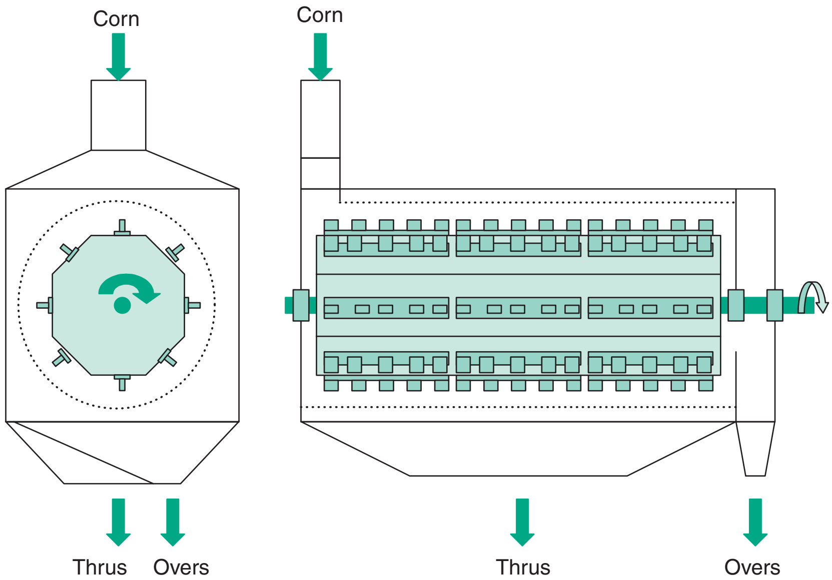

Figure 5 Diagram of a multiple impact/shear-type degerminator.

solvent-extracted, wet-milled oil. Solvent extraction is not practical for most dry mills due to the economy of scale in oil extraction and the high cost of shipping the dry-milled germ to an oil processor. In fact, some smaller mills will forgo pressing and add the germ fraction into the hominy feed. With pressing, oil yield is only 14.2 kg MT^{-1} to 23.1 kg MT^{-1} compared to 28.5 kg MT^{-1} to 30.2 kg MT^{-1} for wet-milled germ. The oil is valued at ~5% more than wet-milled oil because of lower refining losses and refining costs.

Hominy feed is the lowest valued product and is used almost exclusively as an animal feed. In practice, hominy feed, the trashcan of the process, comprises pericarp, degerminator fines, cracked maize, and foreign material and fines removed by the cleaners, pressed germ, out of spec product, and any endosperm fraction that cannot be marketed. There can be considerable variability in the fat and protein contents of hominy feed depending upon each component and the quantity added, although uniformity tends to improve as mill size increases.

Within each category of endosperm material (Table 1), there are nearly an infinite number of potential granulations, which can be marketed as distinct products. Table 2 lists granulation and representative fat content of some of the common products from a dry mill. Product specifications are usually more detailed than were shown (Table 2). Table 3 shows product specifications, in terms of granulation, for two different flaking grit products sold by one dry milling company. Also controlled (and typically specified by the customer) are the moisture and fat contents. One dry mill offers 38 different endosperm granulations and probably produces many more since most large customers provide their own specifications.

Table 1 General product classification of endosperm material showing granulation

Degermed maize endosperm products are used in many processed foods and are processed directly into a variety of breakfast cereals and snack products. They are used in brewing and other fermentation industries to provide carbohydrates to the microorganisms. Industrial uses include hand cleaners, foundry core binders, explosives, adhesives, charcoal briquette binder, textiles, paper, gypsum board, and insulating material.

Impact of Maize Quality and Kernel Characteristics

Probably the single largest variable affecting product yield and product quality is the genetics of the maize. There are considerable differences in the dry milling yields between yellow dent and hard endosperm hybrids as shown in Table 4. Desirable genetically

Thru 3.55 mm	0–1	0–2

determined or genetically predisposed traits are a predominance of hard endosperm, kernel density $>1.30\,\mathrm{g\,ml^{-1}}$, test weight $>0.77\,\mathrm{kg\,l^{-1}}$, large blocky kernels, zero or only one stress crack per kernel, insect and mold free and free from mycotoxins.

Even though potential for these traits is controlled by genetics, some of the traits can be greatly altered by either environment and/or postharvest practices. Hot dry weather tends to increase protein deposition in the kernels and cool weather tends to favor starch production. Stress cracking will increase dramatically with forced-air drying. Stress cracks are formed when the rate of moisture removal from the surface of the kernel (external mass transfer) exceeds the rate of moisture transport from the kernel interior to the surface (diffusivity). This condition causes large moisture gradients to be established in the kernel. The drier side of this moisture gradient shrinks while the inner core of the kernel endosperm is still wet and the only way that the tremendous stresses created by the shrinking can be relieved is for the endosperm to crack. Field drydown or moderate to low drying rates can cause some single stress cracks to be formed, while higher drying rates create multiple nonintersecting cracks or checked (multiple intersecting stress cracks) endosperm. Stress cracks (more than one per kernel) reduces the yield of flaking grits and increases flour yield. High drying temperatures ($>70°C$) can cause the starch to partially gelatinize, resulting in changes in the functional properties of the flour or other endosperm pieces.

There are other quality factors that are primarily influenced by environment. The production of mycotoxins in the field depends upon microbial load and weather conditions. It is desirable to have minimal mycotoxin levels in maize for dry milling since the maize components are often used directly in human food. Mold or insect damage is also primarily influenced by weather or other environmental conditions. Preharvest mold or insect infestation primarily affects kernel development leading to more small kernels as well as yield loss. Pericarp damage by microorganisms or insects can effect the distribution of water during tempering, resulting in germ and pericarp separation problems.

Meeting the criteria for quality described above is no guarantee that the maize will perform in the mill as desired or that the fractions will have the traits desired by the end users. Most mills purchase maize by measuring some combination of the traits listed above, although some mills have prescreened hybrids and offer an "approved hybrid list" to maize producers as a means of minimizing genetic variability. The mills either pay a direct premium to the producer or pay a hidden premium by setting their maize purchase price based upon the mills' need for maize. The result is that their purchase price for maize varies from 100% to 200% local price for US #1 Yellow, with an average of 120% local price. In either case, extensive laboratory testing of each load of maize is performed prior to acceptance.

Functional quality of prime products can also vary based on the mill streams combined to make the salable product. Functional quality is defined as the thermal, rheological, and organoleptic characteristics of the product. For example, coarse meal can be

Table 4 Dry milling yields of nine commercial hard endosperm corn hybrids and two yellow dent samples using a Beall No. "0" Degerminator

produced using a Beall degerminator from four different streams or combinations there of: (1) sifted directly from the tail fraction, (2) sifted from the thru fraction, (3) produced from flaking grits or other grits in the tail fraction, and (4) produced from larger grits sifted from the thru fraction. Each of these methods of producing coarse meal potentially can meet the desired product granulation, fat, and moisture specifications. However, the functional characteristics of the meal is likely to be different for each method of production. Even when the hybrid variability is controlled, variability can exist due to selection of process streams and related "mill balance" issues.

Future Trends

1. *Fastest growth in developing countries*. The dry milling industry is a slow growing industry in the US, with a growth rate of ~2% per year and is most likely related to population growth. It is a mature industry in most industrialized countries and potential for growth beyond this level appears dim. Growth potential appears to be in less developed countries where maize products can be inexpensive ingredients for use in an expanding processed food industry. Dry-milled maize products can also be used to make ready-to-eat cereals and nutritious snacks.
2. *Aging infrastructure in developed countries will lead to paradigm shift*. A major proportion of the US degerminating dry mill capacity is over 50 years old. The basic infrastructure is expensive to maintain or restore. It may be time for a paradigm shift in the industry away from large centralized plants to smaller plants collocated by major end users. Collocation allows for sharing of utilities and infrastructure, minimizes bagged transportation of products, and maximizes technical communication between plants. The milling process can be designed to maximize the production of desired prime products and minimize capital costs.
3. *Hybrid(s) specific processing will become the norm*. The pressure to make traceable quality products for the food industry will continue to mount as consumers become more concerned about food security and food safety. Hybrid specific processing is one way to insure that no undesirable maize enters the processing system. Hybrid specific processing limits the acceptable maize hybrids and identity preserves them through the market channel. The millers can contract directly with the producers or work through various specialty maize merchandizers. This procedure is gaining in popularity and importance.

Wet Milling

S R Eckhoff, University of Illinois, Urbana, IL, USA

Introduction

Worldwide production of maize (referred to as corn in the US) was nearly 600 million tons (Mt) in 2002 of which the United States produced ~40%. Maize is a starch crop, providing needed energy in animal diets and being converted into starch and co-products using the maize wet milling process. It is a near-perfect starch crop: it is readily transportable, easily dried and yields over 66% starch on a dry basis. Over 85% of the starch produced is derived from maize all over the world.

Wet milling is a complex process with a wide variety of unit operations and interdependence between process steps via recycling of process water. An understanding of wet milling begins with the maize kernel and the steeping process.

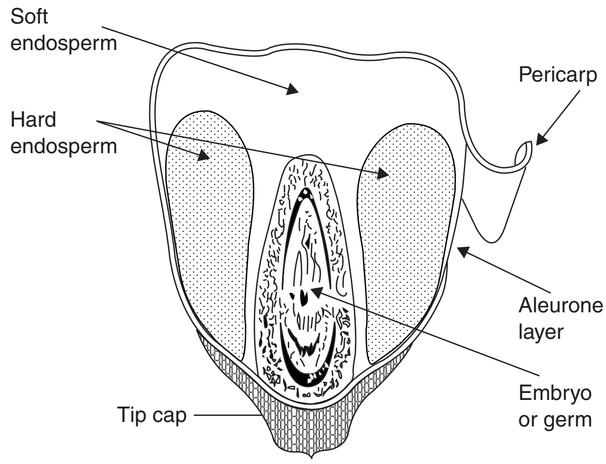

Figure 1 The mature corn kernel, showing component parts. (© Eckhoff SR, Savoy, IL.)

The Maize Kernel

The structure and composition of the maize kernel is covered in detail in **Grain, Morphology of Internal Structure** and so only a pragmatic illustration of the structure and composition of the maize kernel will be given here. The maize kernel is composed of four main parts: the pericarp, the tip cap, the endosperm, and the germ (Figure 1). The pericarp is the outer covering of the kernel and is composed of cellulose, hemicellulose, lignin, and various waxes, all unappetizing components to insects and microorganisms. The pericarp is essentially a plastic grocery bag. The opening in the top of the bag is analogous to the tip cap, the connecting tissue between the kernel and the cob, which is the only natural opening into the kernel. Pericarp consists of dense layers of cells near the surface and wide-open transport cells located next to the aluerone layer. The aluerone layer is the outer layer of the endosperm consisting of large, dense, highly proteinaceous cells, which acts as a semi-permeable membrane, restricting the flow of large molecules in or out of the endosperm. The purpose of the pericarp is exactly the same as the plastic bag: to protect the food material it contains.

The second component of the maize kernel is the germ or embryo, the living part of the maize kernel. It contains all the enzymes and building blocks needed

to quickly begin developing roots and shoots during germination. The germ contains a high percentage of the kernel's oil, water-soluble protein, water-soluble carbohydrate, ash, vitamins, and minerals. However, wet milling processors are primarily concerned with the fact that the germ is high in oil. In the analogy, visualize a sponge saturated with oil. Now put this oil-laden sponge into the bag.

The rest of the maize kernel is endosperm. Endosperm cells are storage cells containing starch granules encased in a protein matrix. The grocery bag is taken with the oily sponge and filled with marbles. A bottle of glue is opened, and the glue poured into the bag, filling the bag, and encapsulating the marbles. The glue sticks the marbles to the bag, the bag to the oily sponge, and the oily sponge to the marbles and glue mixture. It is assumed some of the glue trapped a lot of little air bubbles when it was being poured into the bag and the resulting glue matrix is thin and weak. This is the soft endosperm. Hard endosperm is where the glue matrix is thick and dense. When the glue is dry and a processor's mental picture of the maize kernel is obtained; a plastic bag containing an oily sponge filled with marbles encased in a glue matrix. The purpose of wet milling is to partially dissolve the glue to allow for mechanical separation of the water swollen plastic bag, the swollen oily sponge, the marbles, and the glue. Completed milling yields a pile of nearly empty bags (white fiber), oily sponges (germ), nearly pure marbles (starch granules), and partially degraded glue (maize gluten meal).

The Maize Wet Milling Process

Maize wet milling can be divided into five sections: steeping, germ recovery, fiber recovery, protein recovery, and starch washing (Figure 2). Each of these sections has unique equipment and objectives but all sections are interconnected by the flow of process water.

Steeping

Steeping is the heart of maize wet milling and will be discussed in more detail than the other sections. When steeping is done properly it may be possible to get a good recovery of starch, if downstream processing is performed well. If the maize is not steeped properly, no amount of downstream processing can correct for the poor steeping. Steeping is a process unto itself; a sequence of chemical and biochemical reactions, induced mechanical stresses, leaching, and kernel hydration.

Maize, which has been screened to remove broken pieces of kernels and foreign material is dropped into an insulated hopper bottomed tank, cushioned on the bottom with a layer of water. The broken maize and foreign material are removed because they can plug the screen at the bottom of the tank, which interferes with the circulation of steepwater. The broken maize and foreign material is usually added into the gluten feed product, but may be sold separately to local livestock feeders. A battery of such tanks, interconnected to route steepwater through the tanks in a specific sequence, can vary from as few as 6 to over 50 tanks with sizes from 12.7 Mt to over 633 Mt. The tanks are equipped with a pump that runs continuously, either transferring water or recirculating the water back to the same tank. Recirculation serves the purpose of increasing temperature uniformity. The tanks are also equipped with heaters to maintain a uniform steep temperature of 52°C. Optimal temperature for lactic acid production is 52°C. If the steep temperature drops below ~47°C, yeast begins to propagate and produce alcohol. If the steep temperature gets above 56°C, acetic acid bacteria will begin to dominate the fermentation.

The steeping process takes anywhere from 20 to 48 h to complete. The difference in steep time depends upon the objectives of the wet miller, product mix, and the amount of horsepower used in the mill house. The average steep time in the US is ~30 h, while the average steep time in Japan is over 42 h due to higher relative value of starch compared to the co-products and use of less hp per Mt of maize.

In the vast majority of maize wet milling plants worldwide, maize is steeped counter-currently using a pull system. Dry maize is exposed to the oldest steepwater and the longest steeped maize is exposed to the newest steepwater, process water to which sulfur dioxide has been added (Figure 3). As the steep water goes from the oldest maize to the newest maize in the steeps, the sulfur dioxide level drops significantly, from a high of 1500 ppm to 3000 ppm down to 30 ppm to 300 ppm. When the sulfur dioxide level drops to less than ~300 ppm, the ubiquitous lactic acid bacteria (carried in by the new maize) begin to propagate. This results in the fermentation of glucose to lactic acid at levels ranging from 1% to 3%. Because the lactic acid is high on one end of the process and the sulfur dioxide is high on the other end of the process, the pH changes little during the process and industrially is usually in the range of 3.5–4.2.

Industrial steeping sequences the water flow in order to progress the tanks through the process in a countercurrent manner. Water is pulled from the tank containing the newest maize, the rate determined by the steepwater evaporator capacity. When the steepwater evaporator feed tank is low, sensors open a valve to shunt steepwater from the tank with

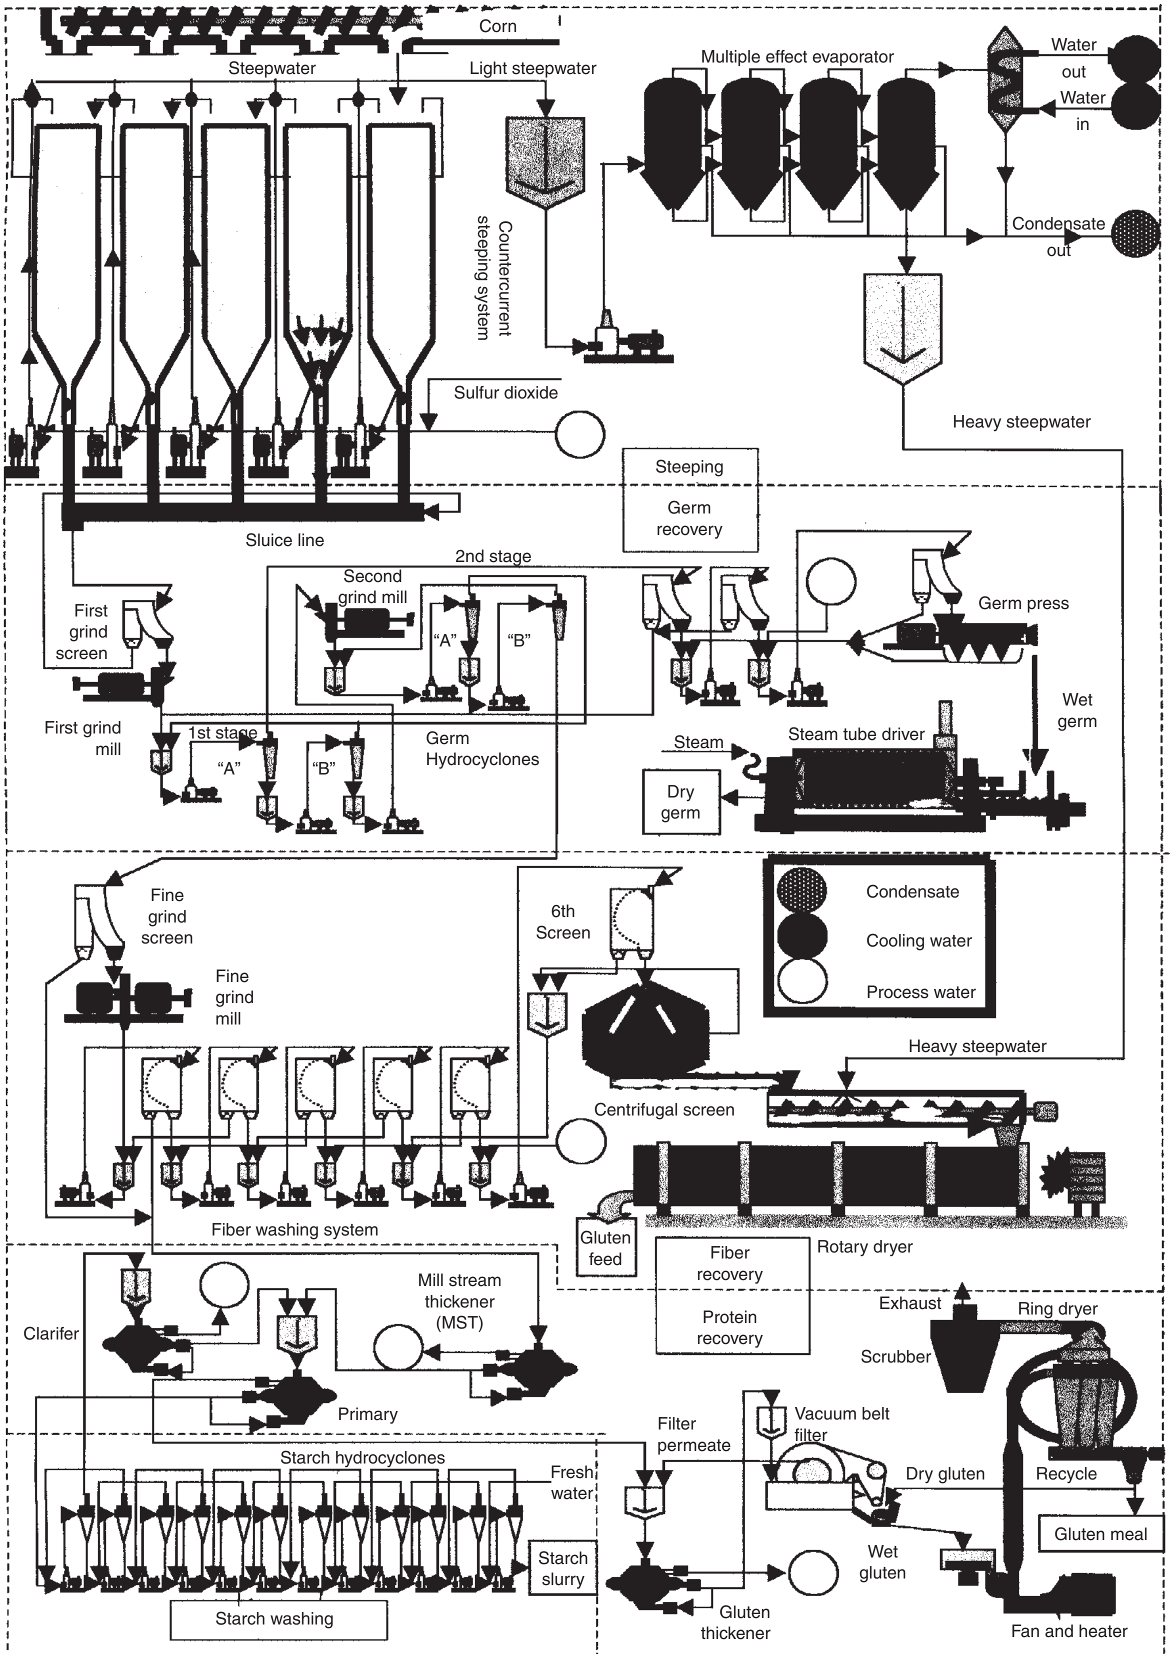

Figure 2 The wet milling process. (© SR Eckhoff, Savoy, IL.)

the oldest steepwater. When the lower limit switch is activated in the oldest steepwater tank, water is shunted from the tank with the second oldest steepwater. This transfer of water continues from tank to tank until the tank with the newest steepwater needs water. This tank is filled with fresh steepwater. When the steepwater evaporator feed tank is full, the tanks in time return to internal recycling of the steepwater.

Eventually the tank with the oldest maize needs to be drained and made ready for milling. Figure 4 illustrates the sequencing required as one tank of steeped maize is drained and the maize sent to the grind mill and the recently filled tank of dry maize is brought into the process. This pattern is continually repeated 24 h a day, 7 days a week. The figure shows the tanks in a circle for simplicity but usually the tanks are in rows.

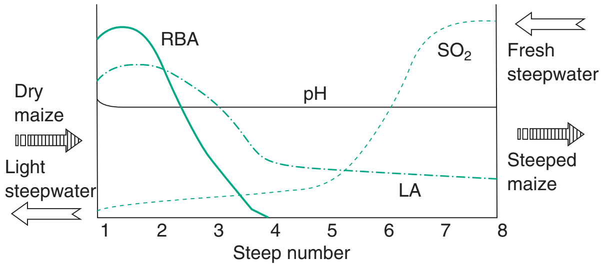

Figure 3 Profile for continuous counter-current steeping. (© SR Eckhoff, Savoy, IL.)

The sulfur dioxide diffuses into the maize kernel during steeping and disrupts the endosperm protein matrix (the glue) by breaking inter- and intra-protein disulfide bonds. The sulfite and lactic acid, resulting from the fermentation, also lowers pH to where endogenous proteases can help solubilize part of the protein matrix.

The steeping process can be broken down into three stages: the lactic acid dominated stage, the sulfur dioxide diffusion stage, and the sulfur dioxide dominated stage (Figures 5 and 6). These three stages are each approximately one-third of the steep time in a properly operated system.

Lactic acid-dominated stage In the lactic acid-dominated stage the key things which occur are: (1) rapid hydration of the kernel in the presence of 1–3% lactic acid to near equilibrium conditions (42–52%, wb), (2) leaching of soluble material from the germ into the steep water causing a concentrating of the oil from 35% to ~50%, (3) fermentation of the soluble carbohydrates coming from the germ and from recycled process water to produce lactic acid, and

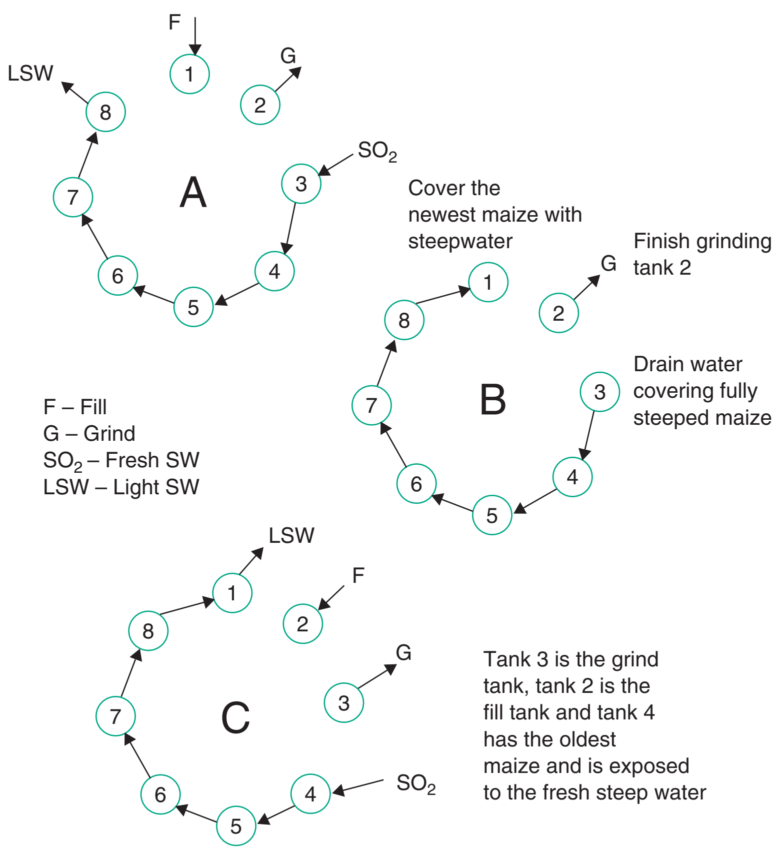

Figure 4 Sequencing of events required to change grind from one tank to another. (© SR Eckhoff, Savoy, IL.)

(4) creation of differential swelling stresses resulting from water uptake which loosens the connecting tissue between the component parts. The lactic acid-dominated stage starts with the introduction of the dry maize into the steep solution and ends when the sulfur dioxide level is high enough to inhibit fermentation.

Sulfur dioxide diffusion stage The sulfur dioxide diffusion stage is called so because the sulfur dioxide that diffuses into the maize kernel during this time is the sulfur dioxide that does the work of disrupting the protein matrix. This second stage is critical to steeping in that it stops the fermentation before producing too much lactic acid (LA levels greater than 1.5% can increase steepwater evaporator fouling) and indicates a point where the sulfur dioxide has a high enough flux to begin making significant inroads into penetrating the kernel. During the lactic acid-dominated stage the sulfur dioxide flux is too low to penetrate very far into the kernel because of the simultaneous reaction and diffusion that occurs. The sulfur dioxide is a highly reactive chemical and in the kernel there are many opportunities to undergo oxidation, acid–base reactions, or become absorbed on the surface of the interstitial pores. Sulfur dioxide that enters during the third stage, the sulfur dioxide-dominated stage, essentially retraces the path through the maize kernel that has already been exposed to sulfur dioxide. During the second stage, there is also continued leaching of this from the germ and the sulfur dioxide begins to react with the protein matrix creating soluble protein, which diffuses from the endosperm into the steepwater. During this time equilibrium moisture levels are reached.

In the third stage of steeping, the sulfite absorbed during the second stage reacts with the protein matrix in the hard endosperm section of maize (the reactions take less than 4 h), so the rate-limiting part of steeping is the diffusion of sulfur dioxide into the kernel. The high level of sulfur dioxide that the maize is exposed to during this stage diffuses into the outer sections of the kernel and is carried downstream into the process to provide microbial control. The high level is also necessary to insure sufficient flux at the start of the second stage. Leaching continues to pull out more of the solubles created by steeping.

After the steep tank is drained, the swollen maize is discharged out of the bottom of the tank into a fast-moving stream of water (sluice water), which carries the kernels to the first grind mill or degerminating mill. The sluice water is recovered by screen and recirculated.

Germ Recovery

The first objective after steeping is to recover the swollen germ. If we visualize the germ as an oily sponge, it is clear that we want to remove the oily sponge from the system as quickly as possible to minimize germ damage, maximize oil recovery, and prevent the oil from getting all over the process equipment and gumming up operations. Mechanical sheer applied properly can separate the germ from the other components with little damage to the germ itself. To accomplish this, the industry uses 61 or 91 in diameter disk mills (224 kW) with specially designed intermeshing teeth (Figure 7) set at a gap setting which allows one or two kernels per handful not to be torn open. This objective operational parameter allows for the vast majority of the kernels to be broken open with minimal damage to the germ. A gap setting that gives 100% germ release would create excessive germ damage.

The milled maize slurry is then pumped through a two-stage hydrocyclone system to recover ~85% of the germ. These germ hydrocyclones are

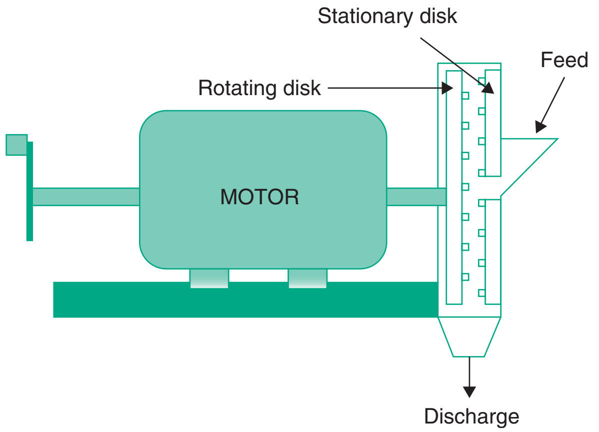

Figure 7 Single disk mill used in germ recovery. (© SR Eckhoff, Savoy, IL.)

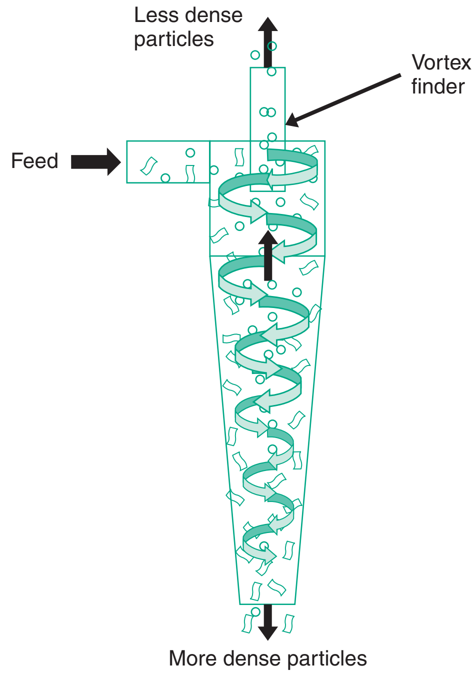

Figure 8 Operation of a germ hydrocyclone. (© SR Eckhoff, Savoy, IL.)

15.25–22.86 cm diameter and 0.6–1.1 m tall. Operating pressures are generally 275–310 kPa with the specific density of the slurry adjusted to between 8 and 9 Baume. At these conditions the free germ (being 42–52% oil) floats and will be forced to the center of the hydrocyclone, away from the wall, where it goes out the vortex finder (Figure 8). The heavier material is forced to the wall of the hydrocyclone by centrifugal force and works its way by gravity to the bottom discharge. In the two-stage hydrocyclone system, stage 1 hydrocyclones are "A" type cyclones designed for a qualitative split between the germ and remaining slurry. Stage 2 hydrocyclones are designed for quantitative recovery of germ, with larger diameter feed and vortex finder connections and are designated "B" type hydrocyclones. Because of flow and capacity differences, there are generally two "A" cyclones for every "B" cyclone. The overflow of the "A" cyclone (light material i.e., germ) and the underflow of the "B" cyclone can be regulated by a flow control valve to achieve the desired split. The overflow of the "B" hydrocyclone is sent back to the feed tank of the "A" hydrocyclone (see Figure 2).

The slurry going out of the bottom of the "B" hydrocyclone is sent to a second single disk mill (known as the second grind mill), with the intermeshing plates set just close enough to make sure that all remaining kernels are properly ground. The reactions proceed at a relatively rapid rate (only minute kernels remain). The resulting slurry is pumped through a second two-stage hydrocyclone system. Just as before, the second hydrocyclone overflow is sent back to the feed tank of the first hydrocyclone. The overflow of the second grind, first stage hydrocyclone is sent back to the feed tank of the first grind, first stage hydrocyclone. With this setup, the germ leaves the hydrocyclone system only from the first grind, first stage hydrocyclone, where it is sent to germ washing. Operation of the germ recovery system is a series of compromises. Attempts to increase the purity of the germ by restricting first grind "A" cyclone overflow increases the recycle and can result in plugged cyclones or a decreased grind. Approximate flow rates out of the overflow is 20% the feed rate for "A" cyclones, 30% feed rate for first grind "B" cyclones, and 30–45% feed rate for second grind "B" cyclones.

Most wet milling plants operate with this two grind, two-stage hydrocyclone system, which essentially gives a minimum of four chances to recover the germ. In-plant experimental data shows that ~85% of the germ is recovered by the first grind hydrocyclones and the remainder by the second grind hydrocyclones. To reduce capital costs, some plants have only a single stage hydrocyclone system after the second grind. Unrecovered germ will primarily be recovered with the fiber or gluten meal. Quantitative recovery of the germ is an economic decision based on the relative values of maize oil and gluten feed and a quality decision based on the sensitivity of the plant's starch product mix.

The germ fraction is counter currently washed to remove residual starch usually in a three-stage process. The washed germ is the water in a germ press and then dried to less than 3% moisture content for shipment to a solvent extraction plant, unless the wet mill has its own extraction facility. The germ must be this dry to prevent oxidation of the oil during transport. The

germ fraction contains 42–55% oil depending on a number of factors including the amount of residual pericarp that floats with the germ, steep time, and maize hybrid or variety. Rotary steam tube dryers are commonly used to dry germ because the exposure time for any individual germ to be in contact with a steam tube is minimal. More recently, fluidized bed dryers are being used because they give more uniform moisture content although it is generally a less efficient drying method. Drier types which expose the germ to temperatures $>80°C$ for extended periods of time should be avoided because the oil will be burnt and extraction efficiencies and oil quality decreased.

Fiber Recovery

The underflow of the second grind, "B" hydrocyclone is sprayed on a 50 μm 120° wedge bar screen (Figure 9) to dewater the mash and to allow starch and protein which has already been released from the fiber to go directly to the mill stream thickener (MST) in the protein recovery section of the process. Material retained by the screen is passed through a double disk refiner mill to release remaining starch from the weakened protein matrix. The double disk mill is similar to the single disk mill used for degermination except that the disks rotate in opposite directions with each disk driven by a separate large electric motor. This arrangement maximizes the sheer that is experienced by the particles. Most double disk refiners used in the US have 91 cm disks operating at 1800 rpm and are equipped with 187 kW electric motors on each disk. Recently some companies in place of the double disk mill have used a 132 cm diameter single disk mill, with 746 kW motor. When operated at 1250 rpm this large single disk mill has disk tip differential velocity similar to the double-disk refiner.

The finely ground slurry is now pumped under pressure onto a six-stage fiber-washing system. The pressure fed screens come in several configurations but most commonly used is the 120° screen (Figure 9). The finely ground fiber–starch–protein slurry is sprayed across the top of the screen at a pressure of ~275 kPa. The pressure and force of gravity causes the fiber to orient parallel to the flow where the wedge bar screen scrapes off residual starch and protein that is still attached to the fiber. The 120° arc of the screen insures contact between the fiber and the wedge bars. At the top of the screen, the pressure accelerates the fiber, pushing it along the surface of the screen. When the screen becomes more vertical near the center, the fiber has decelerated and the principle force on the fiber is gravity. By the time the fiber is on the lower portion of the screen, it has been dewatered

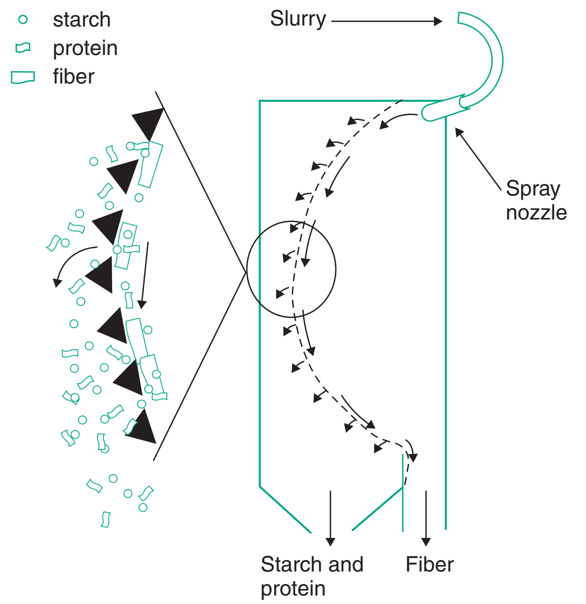

Figure 9 Pressure fed screen with exploded view of the wedge bars. (© SR Eckhoff, Savoy, IL.)

significantly and the fiber bunches up to allow for some more dewatering before it is forced off the screen. Moisture contents are 80–90%, wb.

The first stage screen is a 50 μm screen and is known as the fiber block. The other five screens are 75 μm screens. The theory is that fiber sized between 50 μm and 75 μm agglomerates with other fiber during the initial dewatering and is carried out to the feed house. The 75 μm screens are used because they have a 50% larger open area and less screen area is needed to achieve adequate dewatering in stages 2–6. There are some who consider this arrangement of screens to be a fine fiber generator because the 50–75 μm particles will recirculate between the 50 μm screen and the 75 μm screens until the particle is reduced in size enough to pass the 50 μm screen.

The fiber stream coming off the stage 6 screen is further dewatered using either a screening centrifuge, screw press or both in series. Screening centrifuges can decrease moisture to 65–75%, wb, while a screw press can decrease fiber moisture up to an additional 10 percentage points. This white fiber is blended with already dried fiber and heavy steepwater to form a mixture containing 35–40% moisture, wb, which can be dried to 10–12%, wb, using either a direct fired rotary dryer or steam maize tube dryer. Spent germ (germ meal left after solvent extraction of the oil), broken maize, or spent filter media from syrup production is added dry to the fiber when available. Adding germ meal or filter media to the wet fiber before drying results in excessive dryer smoke. The final product is known as gluten feed.

Protein Recovery

Protein separation depends upon the principle of density difference between the starch and protein. The density of the maize kernel components left at this point is highest for starch and lowest for any cell wall or fiber which passes through the pressure fed screens. (Table 1). The density difference between good starch and protein is sufficient to be able to make a good separation. Seventy years ago, all maize starch, as well as other types of starch was purified by pouring the starch–protein mixture onto tables that were 30–100 m long, about 1 m wide and sloped ~1.04 cm m^{-1}. The starch would settle on the table, while the protein mixture was carried along by the water and ultimately off the end of the table. This technology is still used today in laboratory milling (with much smaller tables) because the starch purity recovered from the starch table is nearly as good as from a wet milling plant. The large amount of space needed for the tables eventually dictated that new technology be developed. The development of the disk-nozzle centrifuge systems for starch–protein separation greatly reduced space requirements and allowed wet millers to grow in size.

Table 1 Density differences in components found in starch slurries

Component	*Density (g ml^{-1})*
Sand, dirt	>2
Starch	1.55
Protein	1.10
Cell walls, fine fiber	1.05
Water	1.00

The principal piece of equipment in any wet milling centrifuge system is what is known as the primary centrifuge. A disk-nozzle primary centrifuge is a continuous centrifuge where a light fraction is separated from a heavier fraction as it is being forced to flow in between rotating disks in a disk stack, with the lighter phase going up between the disks and being discharged as overflow. The heavier phase flows back down the disks and is ultimately forced out of the centrifuge through nozzles located at the periphery (Figure 10). The mill starch is pumped into the centrifuge, at a constant rate, to a spot near the underside of the disk stack. Approximately 1/4 of the way up the disk there are a series of holes, 2.5–5 cm diameter, located every ~30° radially. These holes are lined up in the disk stack to provide an entry point for the feed material. As mill starch enters the space

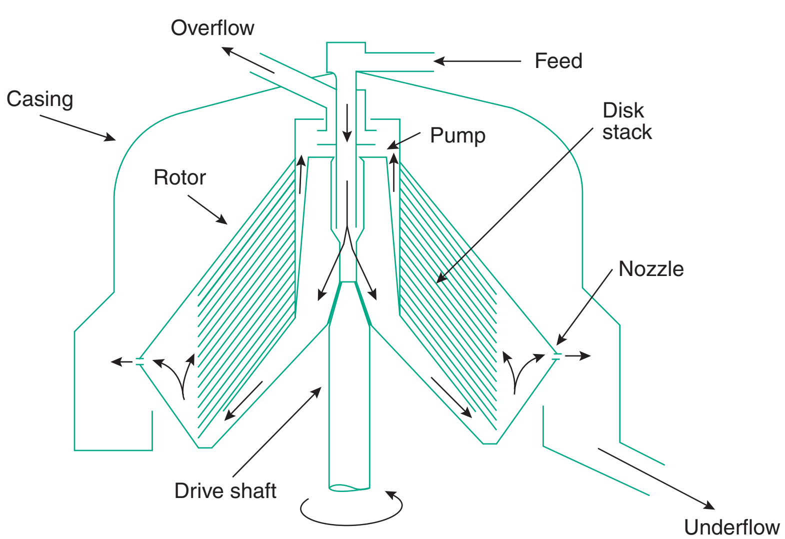

Figure 10 Disk nozzle centrifuge. (Reproduced with permission from Blanchard PH (1992) *Technology of Corn Wet Milling*, p. 393. Amsterdam, The Netherlands: Elsevier Science).

between the disks, the starch, protein, and fiber particles in the slurry are subjected to the centrifugal force caused by the rotating action of the disk stack, the force of gravity and the hydraulic force resulting from pumping (Figure 11). The acceleration of gravity can be neglected at high centrifugal forces. The separating ability of the disk-nozzle centrifuge depends on the relative acceleration of the particle due to centrifugal forces and due to the hydraulic force. For a given particle, the hydraulic force depends upon its position in the flow field. The velocity of the fluid is greatest at the center between the two disks and drops off to zero at the surface of each disk. The force experienced by the particles due to centrifugal action depends upon the mass of the particle, the angular velocity (ω) of the centrifuge, and the settling rate of the particle based on Stokes law.

Figure 11 illustrates the paths taken by light and dense particles. The dense particles are accelerated toward the top surface of the disk by the centrifugal force that is larger than the hydraulic forces even at the center of the channel. As they approach the upper surface of the channel the hydraulic forces continue to decrease due to the decreasing velocity near the top surface of the channel. The centrifugal forces dominate and pull the dense particles toward the outer edge of the disk stack channel. Eventually the dense particles are forced toward the nozzle where it is discharged from the centrifuge. The lighter particles do not have as large a centrifugal force acting on them but the hydraulic force is just as large as for the dense particles. As the lighter particles move toward the center of the channel, the hydraulic forces dominate and the lighter particles are pulled up toward the discharge. Figure 11

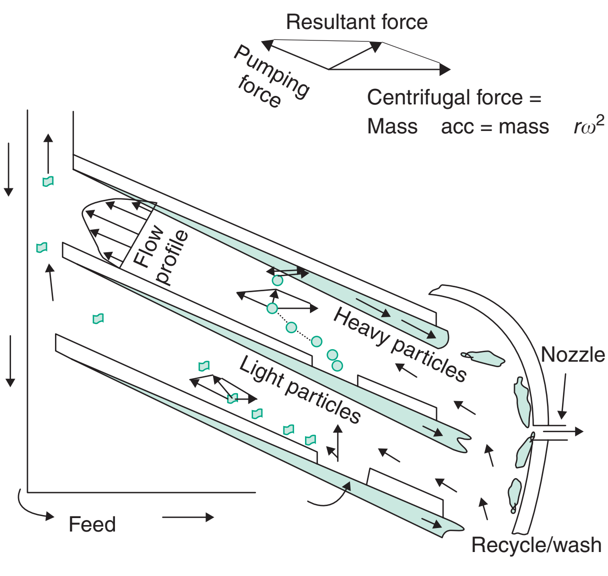

Figure 11 Illustration of the movement of particles between disks in a disk nozzle centrifuge. (© SR Eckhoff, Savoy, IL.)

shows lighter particles and denser particles in different stack channels for illustrative purposes but in actuality their movement is occurring simultaneously in all channels of the disk stack. The primary centrifuge's disk stack is designed to maximize separation between starch and protein at a specified feed rate. Disk stack diameters range from 23 cm pilot plant size to 91 cm commercial size. A 91 cm diameter primary centrifuge can process over 1000 Mt day^{-1} when driven with a 150 kW motor.

If the disk stack configuration and/or pump volume is changed to lower the hydraulic forces relative to the centrifugal forces, the centrifuge can be used to recover all nonsoluble solids. It essentially becomes a dewatering centrifuge. Disk-nozzle centrifuge systems for separating starch and protein can have 2–4 centrifuges. One is the primary while the other 1–3 centrifuges are dewatering centrifuges. The most common centrifuge system used in wet milling is the high-density four-centrifuge system shown in Figure 1. To increase the capacity of the primary centrifuge, MST is used to remove water from the starch–protein slurry coming from the fiber recovery system. The density is increased from ~8 to ~12 Baume. The overflow from the MST is used as the process water going into the steeping system. The overflow from the primary centrifuge is high in protein, nearly 70%, db, but is only 1.5–3.0% solids. Prior to dewatering to 40% solids using a vacuum belt filter, the protein-rich stream is dewatered using a centrifuge known as the gluten thickener, where the gluten stream is dewatered up to 16.5% solids. The overflow from the gluten thickener is used as the process water for germ and fiber washing. The protein cake from the vacuum-belt filter is mixed with dry gluten meal to reduced tackiness and increase the handling characteristics of the wet gluten. It is then dried to ~11% moisture using a ring dryer. The protein content of the resulting gluten meal is established at the primary centrifuge.

The underflow of the primary centrifuge still contains 1.5–3% protein and is sent to the starch washing system, where the starch is washed repeatedly to flushback more of the remaining protein and any fine fiber particles. The overflow of the starch washing system is sent to a dewatering centrifuge known as the clarifier. The overflow to the clarifier is fairly clean water and is used as germ and/or fiber washing process water. The underflow from the clarifier is mixed with the underflow of the MST and is fed to the primary centrifuge. In the four-centrifuge system, the MST, gluten thickener, and clarifier are all designed for dewatering. There are various 2 and 3 centrifuge systems that take out 1 or more of the dewatering centrifuges and have application primarily in smaller plants where capacity is less than can be handled by one primary centrifuge.

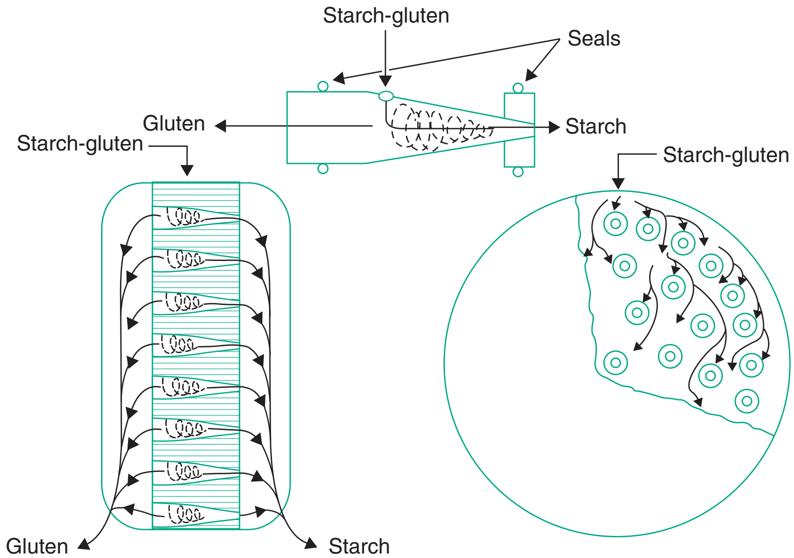

Figure 12 The flow of starch and protein in a 10 mm (Clamshell type) hydrocyclone system for starch washing. (© SR Eckhoff, Savoy, IL.)

Starch Washing

Starch washing is the last step of the wet milling process and is the only place in the whole process that fresh water is added into the system. Starch washing is performed counter currently using 10–14 stages of 10 mm diameter hydrocyclones (Figure 2). Each stage of the starch washing system contains enough hydrocyclones to handle the flow rate of the starch slurry at that point. Approximately 1200–1500 l of fresh water per Mt of maize (2.1–2.6 lbs water per lb of dry starch) is used to counter currently wash the starch to a protein level of 0.25–0.5%. There are several different styles of containers for the numerous parallel 10 mm cyclonettes needed for starch washing. The most popular style still in use in the USA is a clamshell arrangement shown in Figure 12 in which up to 480 individual cyclonettes can be packed into one clamshell and can handle ~890 Mt day^{-1}. Newer units are designed for rapid changing of cyclonettes to minimize downtime of the unit. The underflow of the last starch washing unit is at ~23 Baume. From this point, the slurry can be dried to make unmodified starch, chemically modified and dried or hydrolyzed to make a variety of maize syrups, dextrins or glucose syrups. Drying is usually done with a ring dryer after dewatering the starch using basket centrifuges or vacuum belt filters.

Capital Requirements and Energy Use

Maize wet milling is a capital and energy intensive process (Table 2). The values shown are the purchased equipment and energy for a 2667 Mt day^{-1} wet mill, which produces only dry starch. To calculate the total fixed capital costs, on-site costs need to be known, which can be calculated as a percentage of the purchase equipment costs, based on historical data for processing plants of this type. Fixed capital cost is 1.81 × the on-site costs and as shown in Table 3 is ~$127 million ($US).

Starch dewatering and drying is the largest single user of energy and capital in the wet milling process. However, most maize wet millers do not produce just dry starch but have a wide variety of starch hydrolysate products, as well as modified starches. A similar sized plant dedicated to making fructose, would have a total fixed capital cost of ~$206 million ($US) and a wet mill dedicated to producing ethanol has a total fixed capital cost of nearly $171 million ($US). These values will vary depending upon plant location, local labor costs, and product mix, yet because the equipment suppliers market internationally, the equipment costs will be similar.

Water Flow and Mass Balance

Balancing water flow in a wet mill is critical to profitable operation. In general, any problem can be made a little bit easier by adding more water. The downside of running a dilute wet mill is that you have to get rid of all the water when you are done using it. Wet mills have been bottled up for ~80 years, with all of the water leaving in the products or being evaporated into the air. The average wet mill will spend ~$0.35 per bushel in energy, more than at any single operating expense except the maize itself.

Table 2 Equipment cost and energy use for a 2668 Mt day^{-1} maize wet mill

Item	*kWh Mt^{-1}*	*% of total*	*$ (1000s)*	*% of total*
Corn receiving	4.66	0.54	3500	9.45
Steeping	38.97	4.62	4332	11.69

Fresh water enters the process only at the last stage of starch washing and works its way up through the process, where it washes the primary centrifuge, fiber, and germ. The water, now laden with solubles and some insolubles, ends up as "fresh" steepwater (process water with sulfur dioxide added) moving through the steep battery and finally evaporated to heavy steepwater. Some seal water and rinse water enters the process but usually amounts to less than 8% of the total water added (shown on Figure 13 as extra water). Of the 1200 to 1500 l water per Mt maize, which enters starch washing, ~700 l Mt^{-1} is needed just to hydrate the maize during steeping. Another 420 l Mt^{-1} is needed to fill the void space in the tank so that the maize is not left uncovered. While 1200–1500 l water per Mt maize is a lot of water, 1120 l Mt^{-1} is needed just to be able to run the process.

The mass balance (Figure 13 and Table 4) shows how much water and solids are recycled in the process. Even though the inflow rate of maize and water combined is over 10 000 lbs min^{-1}, individual streams are in excess of 17 500 lbs min^{-1}. Variability in maize characteristics (fraction yields, water-holding capacity, millability, etc.) can cause great swings in process flows. For example, switching from maize with an equilibrium moisture after steeping of maize at 44% to 52%, causes a swing in the water going to the steepwater evaporator of 255 l Mt^{-1} or ~40% of the flow.

Wet Milling Products

Wet milling results in four main products: starch, oil, gluten meal, and gluten feed. Compositional data for these products as well as for specific components of gluten feed is shown in Table 5. Starch is the prime product but co-product value can greatly influence overall plant economics. Co-products make up 30–40% of the total product yield, yet 20–25% of the kernel is processed without increasing value, even though oil and gluten meal have higher value than starch in the US market. There is a wide range of products that can be made from starch (Figure 14), while nonanimal food uses of the co-products are more limited. However, there is an increasing research and commercial interest in improving the existing co-products, finding new industrial uses or extracting nutraceuticals from co-products.

Factors Affecting Starch Yield

Kernel Composition

Based upon $ kg^{-1}, maize oil is the most valuable component of the maize kernel ($0.66 kg^{-1}), followed by high protein gluten meal ($0.30 kg^{-1}), starch ($0.22 kg^{-1}), and gluten feed ($0.07 kg^{-1}). These simple facts often lead to an assumption that maize with enhanced quantities of oil or protein would be desirable in a wet mill. This is generally not true because the change in composition effects mill balance. The mill is designed to process maize of average composition. To handle more germ or more protein the plant often has

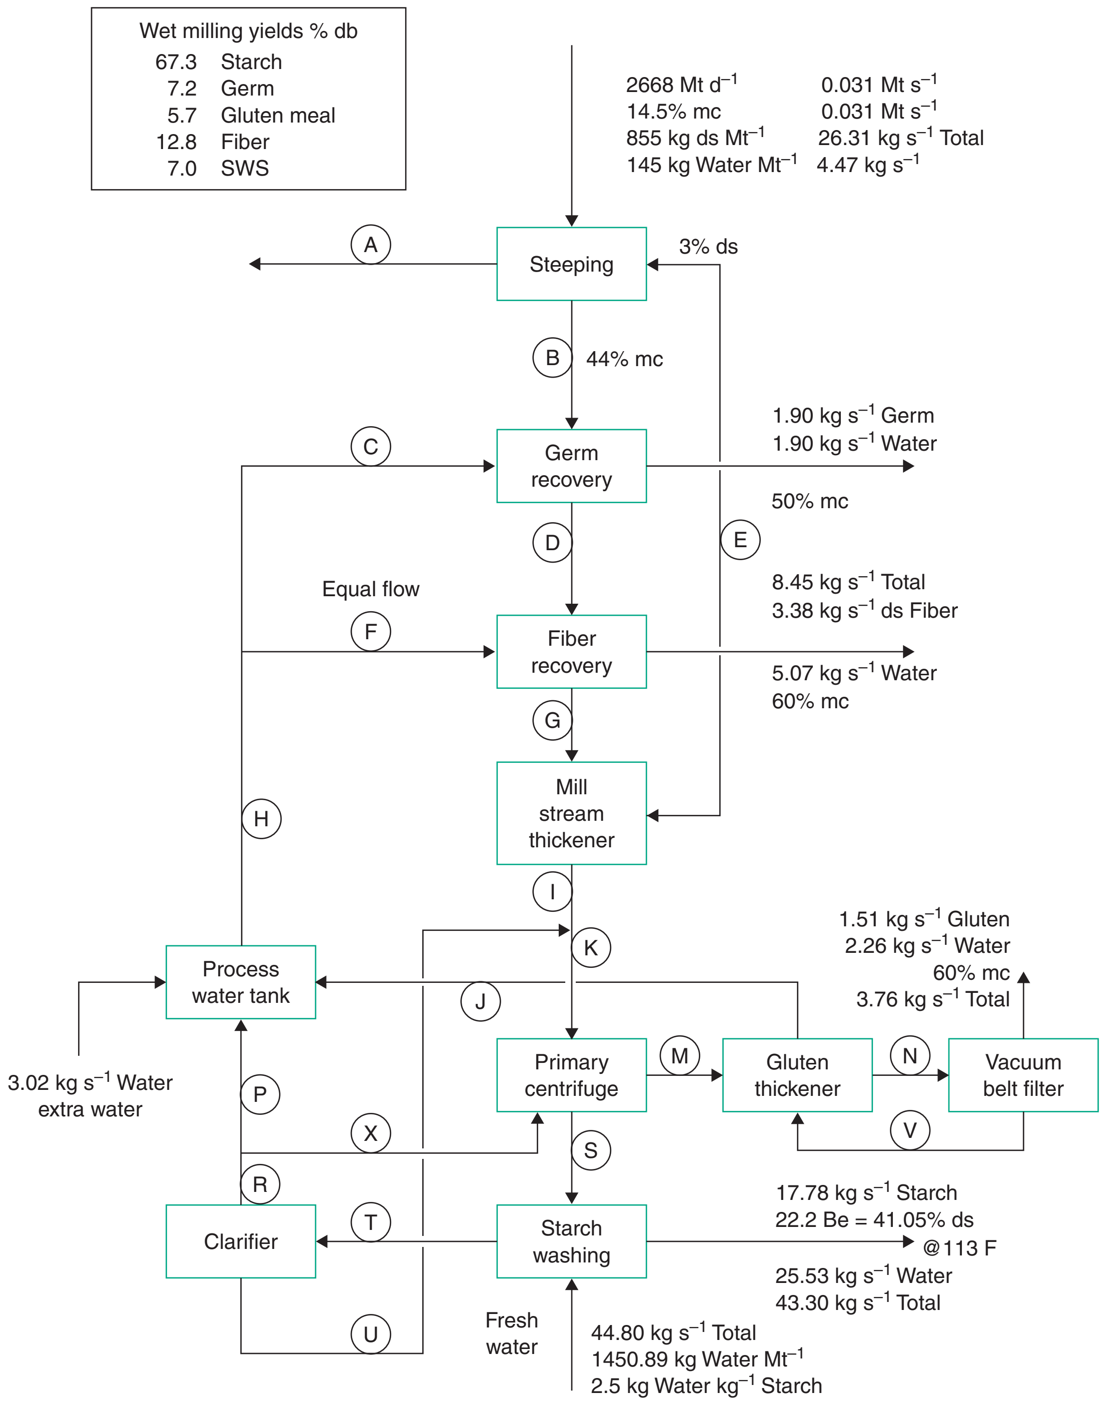

Figure 13 Mass balance on maize wet mill. (© SR Eckhoff, Savoy, IL.)

to decrease its grind rate (the number of bushels processed per day) which increases the processing cost per bushel. It is also possible to expand or redesign wet-milling plants to handle maize with altered compositional characteristics. However, these redesigned mills need to insure themselves of sufficient quantities of reasonably priced enhanced composition maize to justify the added capital.

There are situations where specific mills have economic reasons to desire enhanced compositional characteristics. For example, most of the specialty food and industrial starch plants are smaller, older, land-locked facilities, which cannot economically expand their maize-handling or by-product-handling facilities. High extractable starch maize will allow them to expand production of high-value specialty starches

without expanding their handling capabilities. Japanese wet millers also desire high extractable starch maize due to low by-product values.

Changes in the "quality" of the components, i.e., better amino acid balance in the endosperm glutelin protein or more desirable fatty acid composition, would not affect the mill balance and thus are attractive to wet millers if: (1) any premium they pay for the maize can be more than offset by the increased by-product value, and (2) they can be assured of sufficient quantity of maize to effectively run their facility. In general, wet-milling companies want yellow dent maize with average compositional characteristics.

Test Weight

Higher test weight as controlled by genetics is most often related to the percentage of hard or vitreous endosperm found in the kernel. Hard endosperm takes longer to steep and generally results in less starch release due to the reduced diffusional characteristics of hard endosperm and increased disulfite bonding. Wet millers desire sound, solid kernels, but test weights above 1036 kg Mt^{-1} probably indicated kernels which will require longer steep times and potentially will have lower starch yields. Flint type maize is undesirable, not only for the higher percentage of hard endosperm it contains, but also because it has been

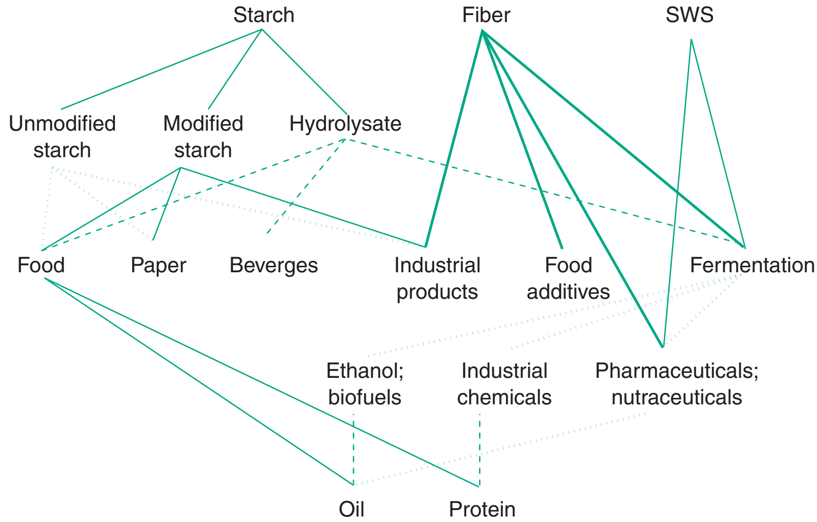

Figure 14 Diagram showing the use of various wet milling co-products in food and industrial products. (© SR Eckhoff, Savoy, IL.)

found to take considerably longer to steep than dent maize, even when diffusional barriers are removed.

The effect of environment on test weight is varied. Hot, dry weather will increase test weight by inducing the formation of a higher percentage of hard or vitreous endosperm. Cool, wet weather has the opposite effect. A recent study found no difference in the yield of starch, even though test weights varied from 700–800 kg Mt^{-1} range to over 1075 kg Mt^{-1} due to weather. Low test weight can also be caused by an early frost causing the maize to never "fill out" or physiologically mature, which has a negative effect on starch yield.

Although test weight differences caused by weather does not affect starch yield, it can affect wet mill economics. Steeping is a volume limited process so that lower test weight means less maize in the steep tank, and if the steep time is held constant; the mill's grind rate is decreased. Test weights below 1000 l Mt^{-1} should be discounted at a rate of \$0.03 per 18 l Mt^{-1} below 1000 l Mt^{-1} to compensate for the loss of grind capacity. Because much of the rest of the wet-milling process is dry solids limited, there is no advantage to having higher test weight maize.

Millability

Millability is defined as the ease of component separation. Genetically some hybrids are easier to process than others. Such hybrids do not contain more starch but milling them results in higher starch yields. The germ floats more readily, the fiber dewaters easier, the bound starch in the fiber is lower, starch and protein are easier to recover and other qualitative as well as quantitative characteristics have been observed. Figure 15 shows the variability in starch yields for 1244 commercially available hybrids (breeder samples) in the Midwest over a 6-year period. Starch yields varied from less than 50–72% with an average near 63.5% and a peak frequency at 66%.

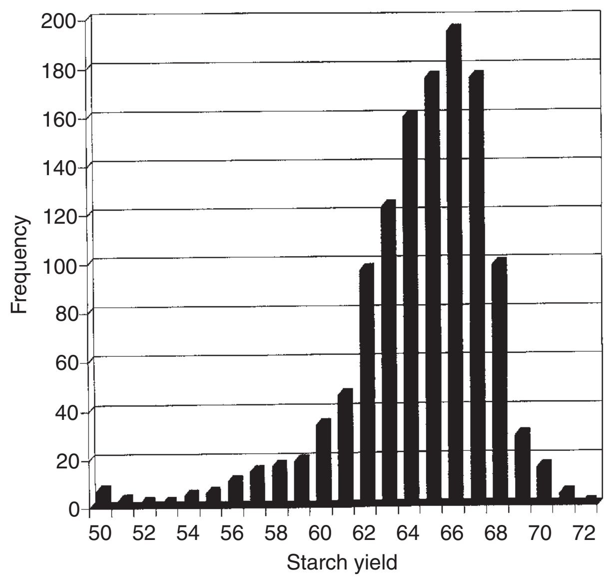

Figure 15 The frequency distribution of maize hybrid starch yields. (© SR Eckhoff, Savoy, IL.)

Mechanical Damage

Mechanical damage to the kernel resulting in broken maize is not desired by wet millers. The broken maize plugs the screens at the bottom of the steep tanks resulting in nonuniform steepwater flow and poor steeping. The broken maize also results in excessive loss of solids into the steepwater and can cause evaporator fouling problems.

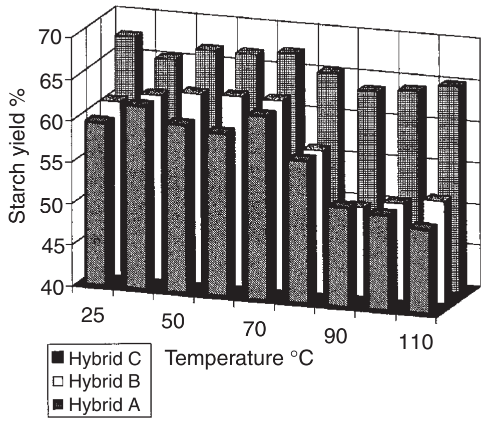

Figure 16 The effect of drying temperature on starch extractability from three maize hybrids. (© SR Eckhoff, Savoy, IL.)

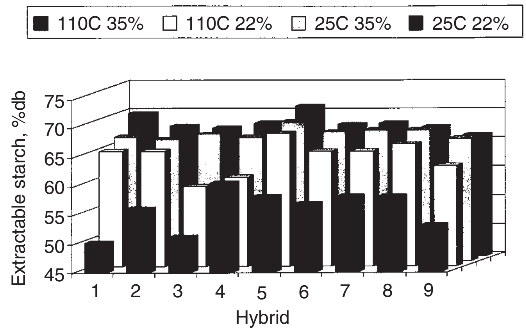

Figure 17 The effect of drying temperature and harvest moisture on starch extractability for nine commercial hybrids. (© SR Eckhoff, Savoy, IL. Reproduced with permission from Singh V, Haken AE, Paulsen MR, and Eckhoff SR (1998). Starch yield sensitivity of maize hybrids to drying temperature and harvest moisture content. *Starke* 49(10): 181–183.)

Drying

Rapid high-temperature drying is the single most detrimental thing that can be done to maize to reduce its starch yield. Numerous studies have shown that drying air temperatures above 70°C can result in partial gelatinization of the starch, protein denaturation and endogenous proteolytic enzyme denaturation.

Figure 16 shows the effect drying air temperature had on the starch yield of three different hybrids. Starch yields decreased as drying air temperature increased above 70°C. As much as 10% yield loss of starch can be observed. Figure 17 shows the wet-milling yields for nine commercial hybrids representing a range of endosperm hardnesses, harvested at two different moisture contents and dried by either ambient air or 110°C drying air. Drying from a higher initial moisture content (>28%) has a severe effect on starch yield. Hybrid variability in sensitivity to drying temperature can also be observed in the data.

Storage

Wet millers have reported over the years that the milling quality of maize diminishes over the course of the season, with considerable difficulty in the summer months. It was perceived that there was some intrinsic loss in quality associated with storage time; possibly due to loss or gain of some enzymatic activity. Wet millers also reported difficulty in the fall in processing new crop maize. They complained of foaming problems and reduced starch yield. These problems generally disappeared after 1–2 months.

Recent studies indicate that there is no intrinsic long-term degradable loss in starch yield due to storage at either ambient conditions or at 4°C until after 4 years. It is likely that the effect of storage observed by the industry in the same crop year is due to the blending of low-quality maize with higher-quality maize to meet minimum grade standards. The amount of microbial and insect damaged maize increases after the spring thaw and accounts for the lower starch yields and greater processing difficulties. The excessive foaming observed with fresh maize is probably related to natural proteolytic activity, which decreases with time.

Milling Unique Hybrid Maize

High Amylose

High-amylose maize is a genetic mutant that has higher levels of the linear form of starch than the 27% normally found in dent maize. Two classes of high amylose are generally grown: Amy 5, which is a group of hybrids containing ~50% amylose and Amy 7, which is a group of hybrids containing ~70% amylose. High amylose starch is produced for a variety of food application and industrially is used in the production of biodegradable packing peanuts. Starch granules of high-amylose maize are generally smaller and more irregularly shaped than normal dent maize starch granules. As a result, high-amylose maize is difficult to mill and recover quantitative amounts of starch. When steeping high-amylose maize, care must be taken to account for the high degree of swelling which occurs. Regular dent maize will swell 60–65% by volume but high-amylose maize will swell 105–128%. In swelling this amount, the maize also absorbs a proportionally larger amount of water. It is usually stated that because amylose has a higher gelatinization temperature, it should be steeped 3°C hotter than normal dent maize. However,

in practice industry does not adjust the temperature. This may be due to the optimal temperature for lactic acid fermentation being 52°C. High-amylose maize requires a longer steep time, has greater difficulty in achieving starch–protein separation and yields only 80–90% as much starch as dent maize.

Waxy

Waxy maize is a genetic mutant that has ~100% amylopectin starch. Amylopectin is the branched form of starch and has a lower pasting temperature than normal dent maize starch. Waxy starch is produced for a variety of food applications. Nearly all of the anticipated demand for waxy maize by wet millers is produced under contract. However, the yield drag associated with waxy maize has disappeared and now that a lot of speculative waxy is being produced, in a year when the contracted acreage does not yield sufficiently to meet demand, speculative waxy is sought out by the wet millers at a sizable premium.

Starch–protein separation is much easier in waxy maize than dent maize, primarily due to the larger granule size of the starch. However, starch yields 5–10 percentage points lower than dent maize. It appears to be an issue with the density of the starch. Even though the starch granules are larger, the absence of amylose in the starch granule apparently does not allow the granule density to be as large. Because waxy starch will gelatinize a lower temperature than dent maize, it is often recommended that it be steeped 3°C cooler (49°C). In practice, the temperature is not adjusted.

High Oil

High oil maize contains ~7% oil primarily by increasing the size of the germ, although, most hybrids have some degree of elevated germ oil concentration as well. Development of high oil maize was primarily for livestock feeding but considerable interest was generated by the wet-milling companies because of the high value of oil. Most wet milling companies had trouble adapting high oil maize into their system because they did not have sufficient germ processing capacity to handle the large influx of germ.

High oil maize hybrids produced by the male sterile pollinator method generally have wet-milling characteristics that are comparable to normal dent maize, with the exception that there was considerably more germ. Starch yields vary from ~55–61%, db. Germs tend to float better primarily because they are larger in size and have higher oil content than normal dent maize. Starch–protein separation does not seem to be affected in the hybrids tested.

Genetically Modified

Genetically modified is a large, diverse, and growing group of hybrids. Most of the commercially available genetically modified maize hybrids have been genetically modified for some agronomic characteristic. These hybrids, to date, have improved or comparable wet-milling characteristics to their nongenetically modified counter parts (Table 6). The generally accepted rationale for improvement of the wet milling characteristics is based on the improved agronomic conditions, i.e., less insect or disease stress on the plants. Hybrids will eventually become available that have been genetically modified to produce nutraceuticals, pharmaceuticals, specialty chemicals, hormones, or to contain enhanced nutrient or functional characteristics. Even if the wet milling characteristics of these hybrids are not altered, alternative fractionation procedures are going to need to be developed to maximize recovery of the high-value product or to

retain the enhanced nutrient or functional characteristics through the milling operation.

Future Trends

There are four basic trends, which emerge when examining the maize wet-milling industry. They are given as follows.

1. The large commodity markets of the recent past have reached maturity and there does not seem to be any new large-scale markets in the near future. The result is that many wet milling companies are looking to higher valued products with much smaller markets and to bio-based products for the industrial markets.
2. There is considerable interest in developing a new technology for wet milling, which does not use sulfite. "E-milling," where specifically designed proteases (enzymes) are used to release the starch from the protein matrix in the endosperm, is one example. Because of government regulations on sulfur dioxide emissions, taste and odor problems associated with co-products exposed to sulfites and potential for new product development, the industry is more willing than they have been in the past (due to the large capital investment they have in place with current technology) to embrace new fractionation technology.
3. The wet-milling industry is undergoing considerable worldwide consolidation. This trend is likely to continue, although probably at a slower pace than in the past three years. Consolidation provides access to worldwide markets, buys capacity, and expertise to diverse product lines and leverages expertise.
4. The industry seems to be slowly moving toward hybrid specific processing, which is the processing of selected maize hybrids with similar characteristics in order to enhance processing throughput, improve quality, and increase food safety via traceability.

Foods from Maize

S O Serna-Saldivar, ITESM-Campus, Monterrey, Mexico

Introduction

Maize (*Zea mays* L.) is the leading grain in the world and staple for large groups of people in Latin America, North America, Asia, and Africa. In contrast to rice and wheat, maize is mainly utilized for animal feeding although direct and industrial food uses are increasing. According to the FAO (2003, http//apps.fao.org) in the year 2000, 387, 111, and 53 million ton (Mt) were used for feed, food, and food manufacture, respectively. Maize is a crop with a remarkable genetic variability; therefore, many specialty genotypes are available. The main specialty corns are popcorn, waxy, high amylose or amylo-maize, sweet, blue, Cuzco, and quality protein maize (QPM). Maize foods are characterized by their unique distinctive flavor not duplicated by any other cereal. The grain is used for production of numerous indigenous foods: maize meal, flour, grits, starches, sweeteners, cooking oil, breads, tortillas, breakfast foods, snacks, industrial alcohol, and alcoholic beverages (*see* **Beverages**: Distilled. **Extrusion Technologies. Fermentation**: Origins and Applications; Foods and Nonalcoholic Beverages. **Maize**: Dry Milling; Wet Milling. **Snack Foods, Processing. Tortillas**). Processed maize products are manufactured from raw materials obtained from three major milling industries: dry milling (*see* **Maize**: Dry Milling), wet milling (*see* **Maize**: Wet Milling), and nixtamalization (*see* **Tortillas**) (Figure 1). The dry milling industry produces an array of refined products widely used by the baking, brewing, snack, and breakfast cereals industries. Most of the starch obtained from the wet milling industry is bioenzymatically converted into maltodextrin, maltose, glucose, and high-fructose syrups. The alkaline cooking or nixtamalization process of whole maize has become important in the United States and other parts of the world due to the increase in popularity of Mexican foods.

Food Uses of Specialty Corns

Specialty corns have been selected due to their unique properties, the most important being popcorn, sweet, high amylose, waxy, blue, and quality protein (*see* **Maize**: Quality Protein Maize) (Table 1). Popcorn has been a favorite traditional snack worldwide for more than a century, whereas sweet maize is one of the most popular canned or frozen vegetables in the USA and Canada. Large quantities of waxy maize that contains more than 95% amylopectin are channeled to the wet milling industry with the aim of obtaining starch that has unique functionality (e.g., low retrogradation).

QPM was developed from the mutant opaque-2 corn discovered in 1963 and contains almost twice

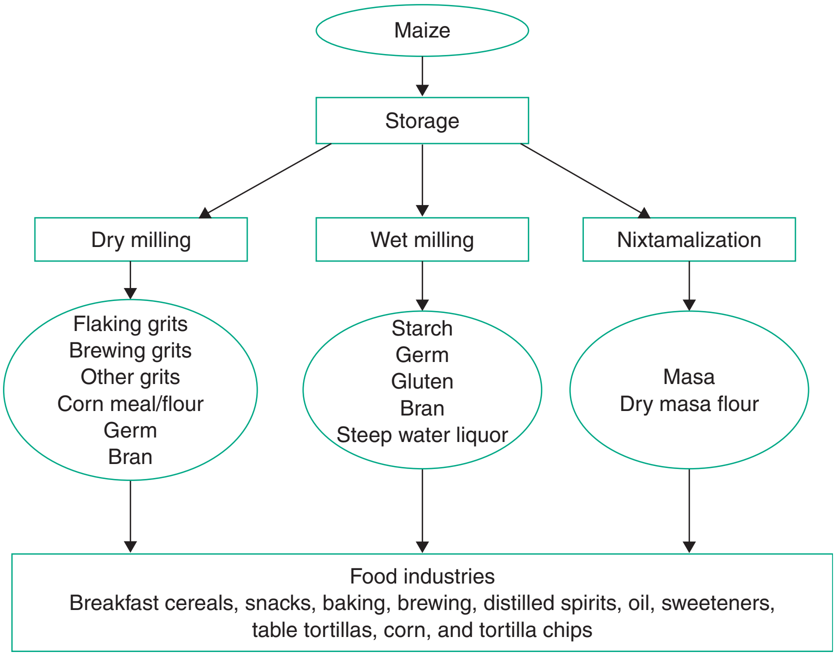

Figure 1 Flowchart of the postharvest management and processing of maize.

as much lysine and tryptophan than regular corn. Thus, QPM-based foods can upgrade the nutritional status of infants, who consume cereals daily in marginal areas around the world. Blue maize has a pigmented aleurone that imparts an intense blue color and a unique flavor. It has been traditionally dry milled for production of flours or meals and also used for tortillas and chips. Blue maize tortilla chips are often served in specialty restaurants and are also sold as organic food. It has high levels of anthocyanins and other phenolics that may have nutraceutical properties (*see* **Nutraceuticals from Grains**).

Table 1 Characteristics and food uses of specialty maizes

Specialty maize	*Food uses*
Popcorn	Special kind of flint corn. Hybrids or varieties with high proportions of translucent, flinty, or vitreous endosperm give higher expansion rates. Expansion volume is the most critical quality factor for popcorn. Most commercial popcorn has a 30- to 40-fold expansion. Popping occurs at ~177°C (350°F), which is equivalent to a steam pressure of 2.5 t cm^{-2} (135 psi) inside the kernel. The water in the kernel is superheated and at the moment of popping converts to steam, which provides the driving force for expanding the thermoplastic endosperm after the kernel ruptures. The pericarp and outer layers of the kernel participate directly in the popping action by serving as a pressure vessel enclosing the endosperm. Popped corn with a spherical shape is called mushroom or ball type and is preferred in the confection industry. The butterfly-type popcorn has a higher expansion, lower apparent bulk density, and better mouth feel; it is preferred for on premises popping.
Food grade yellow and white maize	Mainly developed for alkaline cooking and dry milling. These types of maizes have improved processing efficiency in dry milling and snack food processing plants. These maizes should be hard, medium to large kernels, have high test weight, high density, and a pericarp that is easily removed during processing. In addition, the kernels should come preferably from white cobs. Kernels from pink- or red-colored cobs are high in phenols and yield undesirable off-colors in processed foods.
Quality protein maize	QPM has the opaque 2 gene that is combined with modifier genes that significantly improve the hardness and agronomic performance of the crop. The QPM material has been incorporated into high-yielding hybrids in Brazil, Mexico, and other countries, while open pollinated varieties are grown in Africa and Central America. Harder QPM corns are suited for dry milling and alkaline cooking, while soft hybrids for use in wet milling to produce sweeteners, starches, and alcohol would be desirable since the co-products would be more valuable.
Blue corn	Blue corn is a floury or soft endosperm type that generally grows in long ears (8–12 rows). The aleurone layer contains the anthocyanins that imparts the blue appearance. Blue corn is especially prized as a ceremonial corn by the North American Indian tribes and is currently being used to produce organic flours and foods such as tortilla chips. The blue corn contains higher levels of flavonoids that are currently thought to be excellent source of antioxidants for nutraceutical foods.
Sweet corn	Sweet corns have recessive genes (sugary 1 or su1, sugary 2 or su2) that causes an alteration in the endosperm that results in higher levels of soluble sugars and reduced levels of starch in the kernel. Sweet corn hybrids have been developed specifically to produce corn with desirable color, sweetness, and tenderness.
Baby corn	Special corn varieties are grown and shucked immediately after pollination when the ears are 1–2 in long. These small ears are used as pickles and other tasty snacks in salad bars. Most of the baby corn used is produced in Thailand and exported to Europe and North America.
Waxy maize	Waxy maize is named for the somewhat waxy appearance of the kernel. Waxy maize starch is composed entirely of amylopectin. It is utilized mainly by the wet milling industry. Waxy starch has a higher hot viscosity and produce softer, more stable, and clearer gels due to its lower retrogradation. It also has a higher freeze–thaw stability. Waxy maize is currently being utilized to produce snacks with different textures.
High amylose maize	Also named amylomaize. Expresses high quantities of linear amylose because of the recessive *ae* gene located in chromosome 5. Most genotypes contain amylose from 37% to 65%. Although it is not commercially planted, the amylomaize has potential for the paper, textile, corrugating, and adhesive industries. The high-amylose starch produces rigid opaque gels with potential for the confectionery industry and as a thickener in various puddings and processed foods. It can be used as a binding agent for dehydrated potatoes or as a coating to reduce oil absorption of deep fat fried potatoes. One of the best potential uses of it is for production of biodegradable packaging materials that resembles polystyrene foam used for "plastic peanuts."
Cuzco/cacahuacintle maize	The Cuzco maize comes from an eight-rowed ears that produces the largest known kernels. Cuzco corn grows at high altitudes and produces white kernels with soft endosperm texture and bland flavor. Cuzco corn is mainly used to manufacture Cornnuts™ and Cacahuacintle kernels for hominy and pozole production.

In: White P and Johnson L (eds.) *Corn Chemistry and Technology*. St. Paul, MN: American Association of Cereal Chemists.

Indigenous Maize Foods

Regular and specialty corns are widely consumed in numerous forms in Latin America, Asia, Africa, and the Balkans (Table 2). White maize is generally preferred for foods because it favors the final color of processed foods, but yellow maize is preferred in Brazil, China, Argentina, and some other areas. Most traditional foods are produced from grain that is milled into a meal or flour.

The use of fresh or immature maize on the cob is practiced worldwide. Maize cobs with or without husks are boiled in water or cooked over a fire and then flavored with salt, cream, butter, margarine, and other sauces. In most areas, regular maize is used as green maize.

In Latin America, corn is processed into tortillas (*see* **Tortillas**), "arepas," "couscous," "polenta," porridges), and various meals and gruels (Table 2). The traditional method to process maize into tortillas was developed by ancient Mesoamericans. In the traditional process maize is lime-cooked in clay pots over a fire, followed by overnight steeping. The cooking liquor, called "nejayote," is discarded and then the "nixtamal" is hand-washed and ground into a "masa" with a stone grinder called "metate." Masa is hand-molded or pressed into disks which are baked on a hot griddle or "comal." Tortillas are mainly used as wraps to prepare tacos that hold different types of fillings (beans, various meats, cheeses, and vegetables). Tacos are the symbol of the Mexican cuisine and are known and consumed worldwide. The Mexicans also inherited many other nixtamalized-derived foods such as "tamales," "atole," "pinole," "pozol," and others (Table 2).

Arepas, the national maize bread of Venezuela and Colombia, are traditionally produced from white grits or meal that is moistened, cooked in water, and ground to a dough. The dough is hand-shaped into flat disks that are browned on each side and baked in an oven. Arepas are cut in half and stuffed with meat, cheese, butter, jellies, and other fillings. Stuffed arepas are also fried to produce "hallaquitas," "empanadas," and other foods.

"Chicha" is a prehispanic sacred fermented beverage prepared in Peru and Bolivia in which ground maize is first treated with amylases from germinated maize or saliva and then naturally fermented. Other alcoholic beverages such as "Tesguino" are consumed in Mexico and "Pito," "Talla," and other related opaque beers in Africa (Table 2).

In Africa and Asia, maize is generally dry-milled into grits, meals, and flours for production of flat breads, unfermented and fermented porridges, steamed foods (couscous), and alcoholic or nonalcoholic beverages. Many of the traditional foods are produced from fermented or germinated maize which increases the vitamin content, mineral bioavailabilty, and protein quality. "To," "Pap," and "Sadza" are popular porridges consumed in Africa (Table 2).

The early settlers of North America cooked maize in lye or wood ashes to produce hominy. The alkali effectively removes the pericarp, enhances the palatability and nutritional value of the kernels (Table 3), and transforms the hard raw kernels into a soft, chewable product which could be stored relatively safely. In Mexico, lime-cooked hominy is commonly used for the preparation of "pozole" and "menudo;" both are soups in which the hominy is mixed with condiments and shredded meats (Table 2).

Industrial Processing of Maize for Foods

Most of the maize is first industrially processed by wet milling, dry milling, or nixtamalization (Figure 1). Wet milling produces relatively pure starch, protein, fiber, and germ. Dry milling produces refined endosperm fractions of varying particle size (grits, meal, flour), germ for oil, and sometimes dietary fiber ingredients. Starch and refined dry-milled products are mainly used for the production of snacks, breakfast cereals, syrups, lager beer, and alcohol. Nixtamalization produces dry masa flours, tortillas, and related snack foods that are increasing rapidly in popularity in the USA and other areas.

Food Uses of Starch

More than 90% of the commercial starch is from maize due to the low cost of the grain, high starch content, and high value of the co-products. The refined starch is channeled to various food industries to be used as additive or it is enzymatically hydrolyzed into various types of syrups (*see* **Maize**: Wet Milling). In addition, the co-products are highly valued by the feed and vegetable oil industries. The bran is generally used to feed ruminants, although some is finely ground to produce high dietary fiber foods. The germ is demanded by oil mills to produce the added value refined oil and defatted protein meal. Corn oil is widely used as cooking oil because of its stability and high levels of polyunsaturated fatty acids.

Corn Syrups

In the USA more than 90% of the starch is transformed into syrups (Figure 2). The production and utilization of maize syrups has increased during the past decades because the soft drink industries prefer to use sweeteners instead of crystallized cane or beet

Table 2 Major uses of maize for preparation of indigenous foods

Food	*Description of product and process*
Tortillas	Maize is lime-cooked for 5–30 min and steeped overnight. The cooking liquor is discarded and the resulting "nixtamal" rubbed between the hands to remove the bran. The washed nixtamal is hand-ground with a cylindrical stone and a "metate" or flat stone slab to produce a dough or masa. Pieces of masa are patted into thin round disks that are baked for 30–60 s onto a hot clay circular hot griddle or "comal" to produce tortillas.
Cornbread	Cornmeal alone or blended with wheat flour is processed into dough with water and/or milk and baked. Chemical leavening agents and flavorings (i.e., sugar, salt) are used in some formulations to obtain better texture, volume, and flavor. Many types of cornbread exist around the world.
Arepas	National bread of Venezuela and Colombia. Moistened corn is de-hulled and partially de-germinated in a wooden mortar using a pestle. The meal is cooked in boiling water and stone-ground into masa. Arepas are manually formed into "7.5 cm diameter $\times$ 1 cm thick" flat disks and baked for 2 min on each side on a clay or metal griddle. Arepas are stuffed with meats, cheese, butter, jellies, or other fillings.
To, Sadza, and pap	Staple foods of Africa. Corn meal is cooked in water until completely gelatinized. The porridge is placed in a gourd, cooled for 1 h, and eaten with the fingers and a sauce. Acid (tamarind, lemon), fermentation, or alkali (wood ashes) is added to cooking water to produce acid and alkali porridge. Granulation of the flour, composition, type of sauce, and final consistency vary among countries and tribes.
Canjica	Dish widely consumed in Brazil. Canjica is de-germed corn kernels cooked with sugar and milk, and generally consumed as a dessert or breakfast cereal.
Pozole or menudo	Prehispanic dishes in which one of the main ingredients is whole nixtamal generally prepared from *Cacahuacintle* (white and large kernels with floury endosperm) corn. It is a spicy soup that generally contains peppers, shredded meats, and other spices. The lime or lye cooked corn is mixed with beef stomach, peppers, spices, and onions to produce a soup called Menudo or with shredded pork meat to yield Pozole.
Piki	Traditional dish of American Indians of the southwest prepared from a thin batter of blue corn meal, ash, and water. The batter is cooked on a hot flat stone to form a parchment-like product. Piki can be crumbled, salted, roasted, and eaten-like chips.
Atole and champurrado	Prehispanic breakfast gruels or porridges made out of masa that is diluted in water, sweetened with sugar, and flavored with cinnamon, vanilla, orange leaves, and others. *Champurrado* is produced from cocoa beans, brown sugar, and cinnamon.
Mingau	Brazilian porridge. Corn grits are mashed or immature kernels are cooked in water to produce porridges similar to atole.
Pinole	Corn kernels are toasted on a hot griddle until attaining a brown-golden color, dry milled into a meal, and blended with cinnamon, anise, brown sugar, and other flavorings. The resulting shelf stable mix is diluted with water or milk boiled for $\sim$4 min and consumed as a breakfast gruel.
Pozol	Prehispanic beverage made out of fermented masa. Fresh masa is wrapped in banana leaves and allowed to naturally ferment for 3–5 days. The fermented masa is diluted in water and consumed as beverage. It is considered the major source of nutrients and the "job beverage" for some indigenous groups in south Mexico.
Tamales	Prehispanic dish widely consumed during festivities, Christmas holidays, and weekends. Consists of masa surrounding a filling that has been placed in a wrapper and steamed. In tropical areas tamales are wrapped in banana leaves; hydrated corn husks are used in the rest of Mexico. The coarse masa is blended with lard, salt, chicken or beef broth, and baking powder. Tamales are steamed in a large pot equipped with a rack in the bottom so as to avoid their contact with the boiling water. Before cooking, tamales are packed or stacked in an organized way, because they increase in volume upon cooking. The pot should be tightly covered with the lid to prevent vapor loss. Cooking times vary from 1 to 3 h or until the masa does not stick to the wrapper. The most common tamales contain spicy beans, shredded chicken, beef, pork, fish, seafood, cheese, or sweets (fruit pastes, jelly, nuts, and raisins). Tamales or TV dinners are available in the frozen shelves of the major food markets.
Tacos	This is the most popular way of consuming table tortillas. Soft tortillas are filled with refried beans, shredded meat or poultry, eggs, guacamole, and vegetables. Quesadillas are tacos filled with cheese, while Sincronizadas contain a combination of cheese and ham. Tacos are generally rolled or simply folded.
Flautas	Tortillas are filled with shredded meat, rolled into small cylinders, and fried until crisp. Guacamole, sour cream, and/or cheeses with vegetables are usually spread on top of the flautas.
Enchiladas	Masa for table tortillas is blended with coloring agents (mild red pepper extract, paprika, or artificial), molded, and baked into a red tortilla. Tortillas are fried for few seconds and immediately filled with cheese/raw onions. Some people also called enchiladas the red-colored tortillas filled with shredded chicken or other fillings (mashed potatoe, various types of meats). Shredded fresh cheese and sauces are spread on top of the filled tortillas prior to serving.

Table 2 Continued

Food	*Description of product and process*
Tortillas de manteca or gorditas	Masa is mixed with salt, lard, and tallow. After blending the masa is formed into balls which are allowed to rest for 30 min. Balls are hand-pressed or patted into thick disks which are baked on a hot griddle. These tortillas are usually furnished with beans/cheese and different fillings. Another type called "beany gorditias" are the ones produced by mixing masa with shredded cheese, ground peppers, and refried beans.
Panuchos or papusas	Thick tortillas are filled with refried beans, shredded meats, or poultry with the filling placed underneath the tortilla skin. The product can also be fried. Baked or fried panuchos are generally served with sliced tomato and cooked or cured onions.
Sopes, chalupas, or garnachas	Masa, sometimes blended with lard, is formed into a flat thick disk 1 cm thick and ~10 cm diameter and, while baking, a 1 cm high peripheral wall is formed by pinching. The sope is filled with a combination of refried beans, cheese, shredded meats, poultry, and vegetables (lettuce, tomato, radishes, onions).
Tlacoyos	Masa is flattened into thick disks and refried beans placed in the middle of the formed cake. Both sides are folded to cover the beans and to impart the typical tlacoyo configuration (oval-elongated shape). Tlacoyos are baked on both sides onto a hot griddle and usually served with green sauce and dairy cream. Blue corn tlacoyos are very popular in central and south Mexico.
Empanadas	Masa, sometimes mixed with baking powder, is formed into small balls and pressed into thin disks. The preformed masa is filled with shredded meats, beans, cheeses, and folded. The rim of the folded (half-moon) tortilla is sealed by pressing with a fork and then fried.
Tostadas and taco shells	Tostadas are tortillas fried in the flat form and widely used as the base to hold different fillings. For their preparation, nixtamal and red-paprika peppers or annatto is stone-ground into a coarse masa. Today coloring agents are also used. The red- or orange-colored masa is baked into a tortilla and then fried into a tostada. Tostadas are the base for the preparation of wide array of meals. It is very common to consume tostadas with refried beans, cheese, shredded meats, and vegetables such as lettuce, tomato, onions, peppers, and radish. Taco shells are the American version of tostadas with the only difference that they are usually fried bent (U form) and rarely colored. Regular and low-fat tostadas and taco shells are available in grocery stores in Mexico and USA.
Pimes	Mayan dish. Corn masa is blended with salt and lard and sometimes ground peppers. The masa is formed into thick disks that are baked on a hot griddle previously greased with lard.
Pemoles	Mayan dish. Black beans are smashed, fried, and sun-dried. Then they are mixed with masa to form a thick black tortilla disk. The disks are fried and served with picante sauce.
Joroch	Mayan dish. Small masa balls are cooked with smashed beans and the resulting blend served with ground squash seeds.
Tobi holoch	Mayan dish. Annato seeds are fried in lard until release their color. The resulting colored lard is mixed with masa and salt. Alongside, ground meat is cooked with finely ground onion, tomato, and sweet peppers. Masa is hand-formed into an oval shape and the filling placed in the center. The masa is folded, wrapped in banana leaves, and steam-cooked.
Salbutes	Corn masa is blended with salt and wheat flour. Hand-made tortilla disks are fried and then spread on top lettuce or cabbage, shredded poultry, cured onions, and sliced tomato.
Tortilla soup	One of the most popular Mexican soups. Contains up to 15 different ingredients in which the main one is fried tortilla strips. Garlic, onion, and tomato are ground into a sauce and diluted and simmered in chicken broth. Salt, peppers, and other seasonings are added. Few minutes before serving, the soup is reheated, and fried tortilla strips, cheese cubes, and avocado incorporated onto the top of the mix.
Chilaquiles	Prehispanic dish very popular in all Mexico. The nahuatl word derives from *chilli* (= peppers) and *quilitl* (= edible) herbs. Chilaquiles are prepared by first producing a sauce based on tomato, onion, peppers, garlic, and salt. Then stale or leftover tortillas cut into pieces and fried until crisp and incorporated into the sauce. Shredded chicken, cream, and cheese are usually placed on top of the chilaquiles.
Chicha morada	Prehispanic sacred beverage prepared in Peru and Bolivia. Salivated or germinated corn flour and water is heated to 75°C, thoroughly mixed for 1 h, and cooled. Upon sedimentation the upper layer called "Upi" is placed in another pot and simmered for several hours until it is caramelized. This product called "misqui kheta" is allowed to cool, combined with more upi, and fermented for 48–144 h to produce a clear, yellowish effervescent beverage. Chicha morada is made from blue corn that is cooked in water with sugar for several hours. The mixture is filtered and the purple liquor is blended with fruit juice (i.e., pineapple) and consumed as a beverage.
Tesguino	Alcoholic beverage produced in Mexico. Corn is soaked in water for several days, drained, germinated, ground, and steeped in water until the mixture turns yellow (8 h). Then, the liquid is filtered, ground leaves, beans, and legumes are added. Fermentation produces an opaque, sour beer with 3–4% alcohol.

Table 2 Continued

Food	*Description of product and process*
Pito	Nigerian alcoholic beverage. Corn is soaked in water, drained, and held in a moist chamber for 5 days germination. The corn malt is mashed for 6–10 h, cooled, and sieved. The filtrate sours due to microbial fermentation. Then it is concentrated and inoculated with starter from a previous batch and allowed to ferment overnight. Pito is a light brown, slightly bitter, sweet–sour alcoholic beverage.
Talla	Ethiopian alcoholic beverage. A slurry of toasted, ground, and cooked maize flour is mixed with flavorings, pieces of freshly baked flat bread, and wheat or barley malt. After a day, the mixture is diluted with water, fermented for 5–7 days, and filtered. Talla has a smoky flavor and a tan to dark brown color.
Ogi and ugali	Fermented porridges widely consumed in Africa. Corn kernels are steeped and fermented for several days. Steeped grain is wet milled, slurried with water, and sieved. The slurry is allowed to ferment longer. The fermented sediment is separated and boiled in water to yield ogi porridge that is consumed warm or cooled to form a gel or pudding.
Polenta	Popular dish in Italy and South America. De-germinated corn grits are cooked in water until gelatinized, mixed with tomato sauce, cheese, meat, etc., and baked.
Couscous	Ground corn is kneaded with water until the flour particles agglomerate when forced through a coarse sieve. Then the particles are steamed. At intervals the couscous is removed, resieved, and returned to the steamer. The cooked product is consumed with a sauce. In Africa, ground baobab leaves, peanut butter, okra, etc. are mixed with the couscous during the final stage of steaming when it is to be dried and used as a convenient food.

sugar. Maize sweeteners are preferred over sucrose because they readily dissolve in water and are easier to incorporate into soft drinks, are easily flavored, and impart a fruit flavor to beverages and foods. The high-fructose corn syrup (HFCS) containing 90% fructose impart 1.7 times more sweetness than sucrose at equivalent concentrations.

The various types of syrups are manufactured from acid hydrolysis or enzymatic conversion or a combination of these two processes. The industrial production of amylolytic enzymes allowed the production of better-quality low DE syrups and the production of glucose syrups with high DE or sweetness. The industry evolved with the commercial availability of heat-stable α-amylase and amyloglucosidase that could transform practically all the starch into glucose. The greatest technological developments were the utilization of immobilized glucose isomerase and the continuous separation of glucose and fructose by moving bed chromatography. With these developments, the industry is capable of producing the popular HFCSs.

Low DE syrups (maltodextrins) The low DE or maltodextrin-rich syrups are industrially produced by acid hydrolysis or by α-amylase conversion. These syrups are the easiest to manufacture and are the first step for the production of maltose, glucose, and HFCS. The acid hydrolysis is performed in 35–40% starch suspensions using a 0.02–0.2 N hydrochloric solution in a pressurized reactor. A higher acid concentration or longer process time can yield undesirable compounds such as methylfurfural, formic acid, and/or off-flavors and off-colors. That is the reason why use of this technology is now limited. The most popular way to convert starch into maltodextrins is via the utilization of α-amylases or liquefying enzymes. Today, heat-stable α-amylases are used because they require shorter incubation. Their optimum activity is achieved at pH of 6.5 and temperatures of 90–100°C. These syrups with 10–20 DE are very viscous, rich in maltodextrins and low in sweetness; therefore, they are mainly used as thickening agents. Regular cornstarch produces haze formation, whereas utilization of waxy starch, more stable syrups. A high dextrin syrup adjusted to contain 15% solids, and pH 5–6 is used as substrate for CGTáse for cyclodextrin production. These cyclic oligosaccharides are composed of six, seven, or eight glucose units linked by α-(1–4) linkages to form α-, β-, or γ-cyclodextrins, respectively. Cyclodextrins have several useful properties. They have good chemical stability to bases and weak acids and good thermal stability because they melt at temperatures of 270°C. Their hygroscopicity is low and are resistant to amylolytic enzymes. In addition, they are used to enhance chemical stability and reduce volatility of complexed molecules, and mask unpleasant odors and flavors.

Maltose syrups Regular and high maltose corn syrups are manufactured starting with a low DE syrup that is treated with β-amylase or a combination of

pullulanase and β-amylase (Figure 2). β-Amylase works best at pH 5 and 55°C. The utilization of only β-amylase yields a syrup with 50–55% maltose, while the use of de-branching pullulanase and β-amylase syrups results in syrups with ~80% maltose. Regular and high maltose syrups are widely used as flavorings for breakfast cereals, beverages, and other food products.

Glucose syrups For production of 90 DE glucose syrups, low DE syrups are treated with amyloglucosidase or saccharifying enzyme at pH 4.6–5.2 and a temperature of 55–60°C (Figure 2). The syrup is refined and clarified through columns of activated carbon and ionic resins with the aim of removing minerals, pigments, soluble protein, fat, and enzyme resistant starch. Glucose syrups are utilized as sweeteners for soft drinks, baking formulations, and as a source of fermentable carbohydrates for light beer, alcohol production, and yeast-leavened baking goods. Crystallized dextrose can be produced by concentrating the syrup to 75% solids, adding glucose, and gradually cooling to drop the temperature to 20–30°C for several days.

High-fructose corn syrups HFCSs are manufactured starting from a 90 DE glucose syrup that is further treated with immobilized glucose isomerase (Figure 2). The refined glucose syrup is de-aerated and treated with magnesium sulfate so as to assure oxygen removal and the sequestration of calcium that lowers enzyme activity and half-life. There are three major types of HFCSs: 42, 55, and 90. The 55 and 90 HFCSs are produced from the 42 HFCS. The 42 HFCS is industrially produced by passing glucose syrup through a reactor with glucose isomerase. The

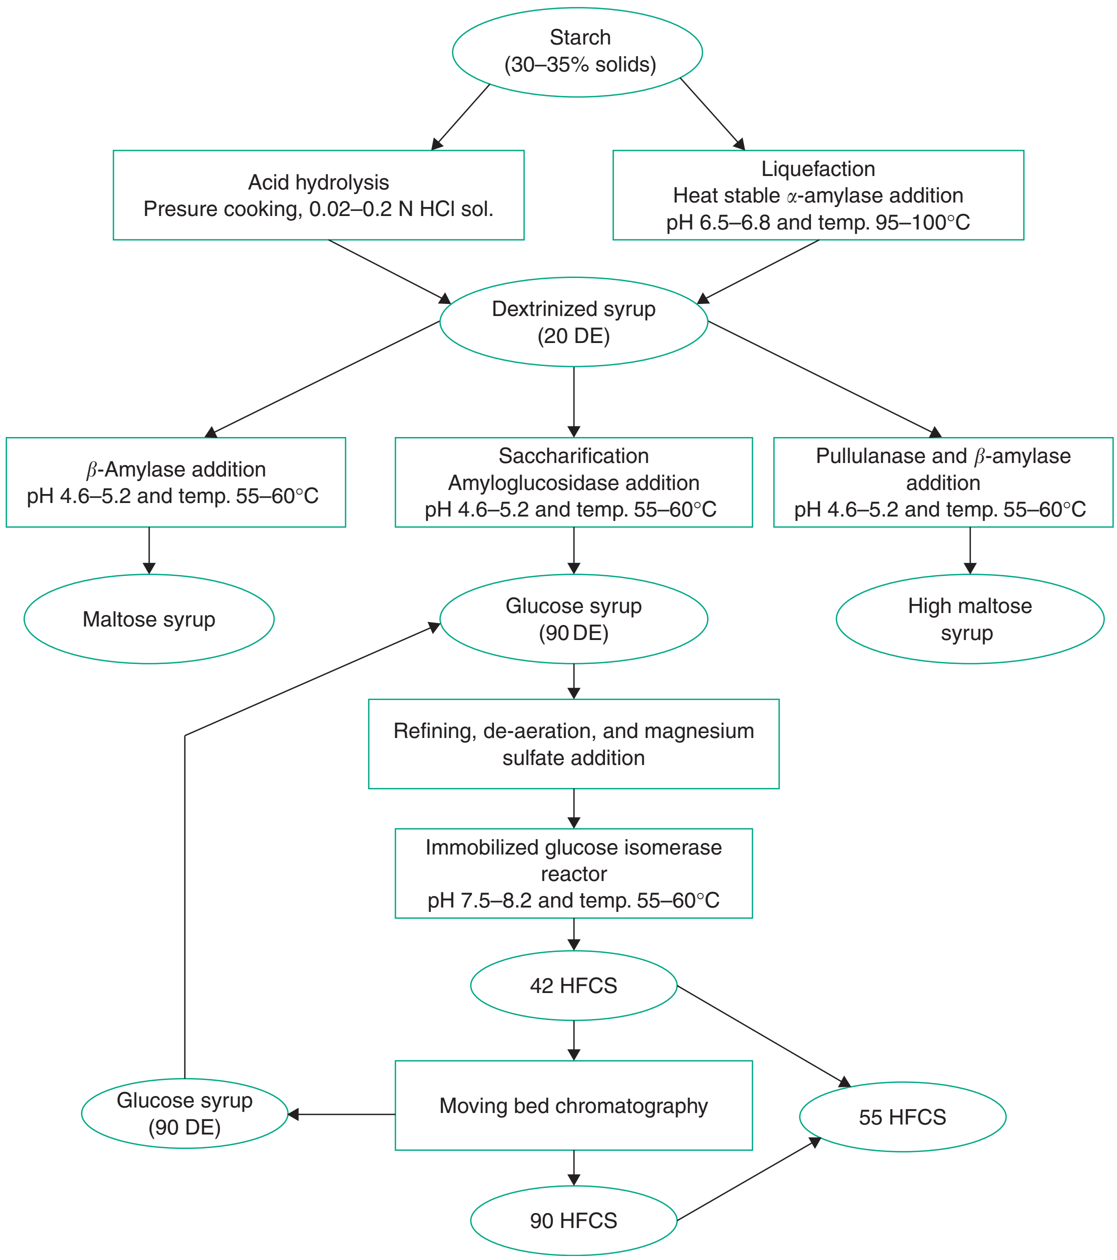

Figure 2 Flowchart of industrial processes to produce corn syrups.

optimum operating conditions are pH 7.5–8.2 and 55–60°C. The substrate flow rate is controlled so as to convert 42–45% of the glucose into fructose. The 90 HFCS is obtained after separating fructose and glucose in a moving bed chromatography system that produces two syrups with ~90% of each type of sugar (Figure 2). If desired, the glucose-rich syrup can be converted into 42 and 90 HFCS as explained before. The 55 HFCS is manufactured by mixing 42 and 90 HFCSs. The 90 HFCS has ~1.7 times more sweetness than the other HFCSs and crystallized sugar. HFCSs are used as substitutes of table sugar especially in soft drinks. The main advantage of using HFCS is that they readily dissolve in water, are easily flavored, and impart a sweet fruit flavor to beverages and foods.

Food Uses of Dry-Milled Fractions

Endosperm products from corn dry milling, ranging from large grits to flour, are widely used by brewers, snack food, and breakfast cereal processors.

Flaking grits Flaking grits are large (US 3.5–6 mesh sieves) endosperm particles obtained after maize degerming (*see* **Maize**: Dry Milling). These large pieces of endosperm are almost exclusively used to manufacture cornflakes by the traditional way, the most popular ready-to-eat breakfast cereal. The fundamental process has remained relatively unchanged over the past century (*see* **Cereals**: Breakfast Cereals). Yellow maize is preferred because of its stronger flavor and rich golden color after toasting. The flaking grits are pressure-cooked in rotary cookers for 1–2 h with syrup, sugar, nondiastatic malt, salt, and water. The cooked grits are conveyed to a delumping equipment and dried at 66°C to lower its moisture to 20%. Then, the grits are equilibrated for 6–24 h in a bin and flaked through a pair of counter-rotating rollers. The resulting soft flakes are toasted in a gas-fired oven in order to develop the crisp texture, brown color, and the characteristic flavor. The flakes are sprayed with nutrients and equilibrated. The typical nutritional value of cornflakes is presented in Table 3. Sugar-coated flakes are made by the same process, but the sweetener is sprayed onto the flakes after toasting. Cornflakes can also be made from meal or grits that are extruded to produce pellets (*see* **Extrusion Technologies**).

Corn grits Corn grits are low in fiber and contain less than 1% oil. Grits of various granulations are widely utilized by the snack, breakfast cereal, and brewing industries. In the USA, maize grits are consumed as a side dish for breakfast (Table 3). The grits are cooked in boiling water for 10–25 min and then seasoned with butter or margarine. Instant or precooked maize grits which require only 5 min cooking are popular. In southern states, white maize grits are preferred over the yellow counterpart because they possess a bland and sweeter flavor.

Traditionally, the brewing industry has been the largest user of corn grits. Grits are used as a source of inexpensive fermentable carbohydrates. Brewer grits have a size range which facilitates filtration of the wort. The most desirable grits contain less than 1% oil, ash, and fiber, have optimum particle size distribution, and high malt extracts.

Whole ground maize and refined grits are used to produce alcoholic beverages. Straight bourbon whiskey is obtained from distillation of a fermented mash containing at least 51% maize in the United States. The distillate is aged for 2–10 years in wooden barrels, blended, and bottled.

Maize alone or in combination with other cereals and ingredients is often used in ready-to-eat breakfast foods (*see* **Cereals**: Breakfast Cereals). Grits, meals, or flours are cooked to gelatinize the starch, denature the protein, and produce a dough, which can be processed into flakes, shreds, granules, puffs, or collets. The nutritional value of several maize-based breakfast cereals is summarized in Table 3. Desirable flavor, aroma, and texture are usually obtained by controlled toasting. Currently, most new breakfast cereals are prepared by continuous extrusion and puffing which has economic advantages. Maize flour or meal is moisturized, combined with starches, flavorings, and coloring agents to prepare a wide array of products. Extruded gun-puffed cereals are still one of the most popular types of ready-to-eat breakfast cereals. The puffing gun is charged with equilibrated collets, sealed, and heated to increase the pressure to 150–200 psi. The pressure is suddenly released and the material explodes from the gun. The degree of puffing varies according to temperature and pressure. The expansion varies from 10 to 16 times.

Products that require less expansion are generally oven puffed. Puffing is achieved by exposing the product to radiant heat on a belt or by tumbling it in a rotating cylinder. This process produces a three to fourfold expansion. The oven puffing operation requires the correct balance of moisture content and oven temperature to achieve the desired puffing.

Extruded snacks are a growing segment of the maize-based snack market (*see* **Extrusion Technologies. Snack Foods, Processing**). Corn meal or grits are processed through extrusion cooking and puffing to produce maize curls, puffs, and balls (Table 3). The shape of the puffed extrudate is determined by the die, operational temperature, cut-off knife speed, and other factors. Extrudate expansion is closely related to product texture and is affected by the viscoelastic nature of the material and the amount of moisture in the material flowing through the extruder die assembly. The extrudates are baked or fried, flavored, and packaged to produce the final ready-to-eat product. Mouth feel is affected by oil content of the products.

Collets or half products can be produced by conventional methods, i.e., macaroni presses, or by using a combination of two extruders. The first extruder cooks the raw ingredients while the second cools, forms, and sizes the extrudate into dense collets, which are dried, stored, and then baked or fried into the final product called third generation snacks. Baked collets are crisp with a light, crunchy texture. Deep fat fried collets are crisp with smoother texture due to the uptake of the oil. Pre-extrusion moisture content of the meal is critical in determining the characteristics and texture of the product. As the moisture content is increased, extrusion cooking temperatures generally drop, and a dense, less expanded product is obtained. High moisture meals produce hard, dense

extrudates that are generally fried. Meals with low moisture produce expanded extrudates that are generally baked to form a light textured puffed snack.

Large, state-of-the-art plants commercially produce instant arepa flours that require only hot water to produce the dough. Maize grits are cooked and then passed through flaking rolls to gelatinize the starch. The flakes are dried and ground into flour with acceptable granulation. With precooked maize flour, arepas can be prepared in ~30 min instead of 12–24 h required by the traditional process.

Maize meal and flour Corn meals and flours have smaller granulation than grits and are popular products because of their long shelf-life, freedom from black specks, and bright color. Maize meal is often enriched with thiamin, riboflavin, niacin, and iron. It is used to produce an assortment of chemically leavened baked and fried products such as corn bread, muffins, pancakes, cornsticks, fritters, hush puppies, and spoon bread (Table 3). Most maize bread formulations contain wheat flour, chemical leavening agents, sugar, salt, milk powder, and other ingredients. Maize does not have a functional gluten so wheat flour is included to give the dough more elasticity and hence produce a more aerated lighter product. Hush puppies are produced from a chemically leavened dough which contains maize meal, wheat flour, eggs, milk, salt, onions, and tomato. Pieces of dough are deep fat fried for 2–3 min. Maize flour is also widely used as an ingredient in many formulations, for breadings and batters and as a binder in processed meats.

Food Uses of Nixtamalized Products

Three basic types of products are industrially produced from lime-cooked maize: table or soft tortillas, corn chips, and tortilla chips (Figure 3). Corn and tortilla chips are primarily produced and consumed in developed countries, where they have an important share within the salted snack food market.

Table tortillas Tortillas and masa products constitute the staple food for large population in Mexico and Central America. Tortillas are produced using traditional and industrial processes. Tortillas are the main source of energy, protein, calcium, and other important nutrients in Mexico and Central America

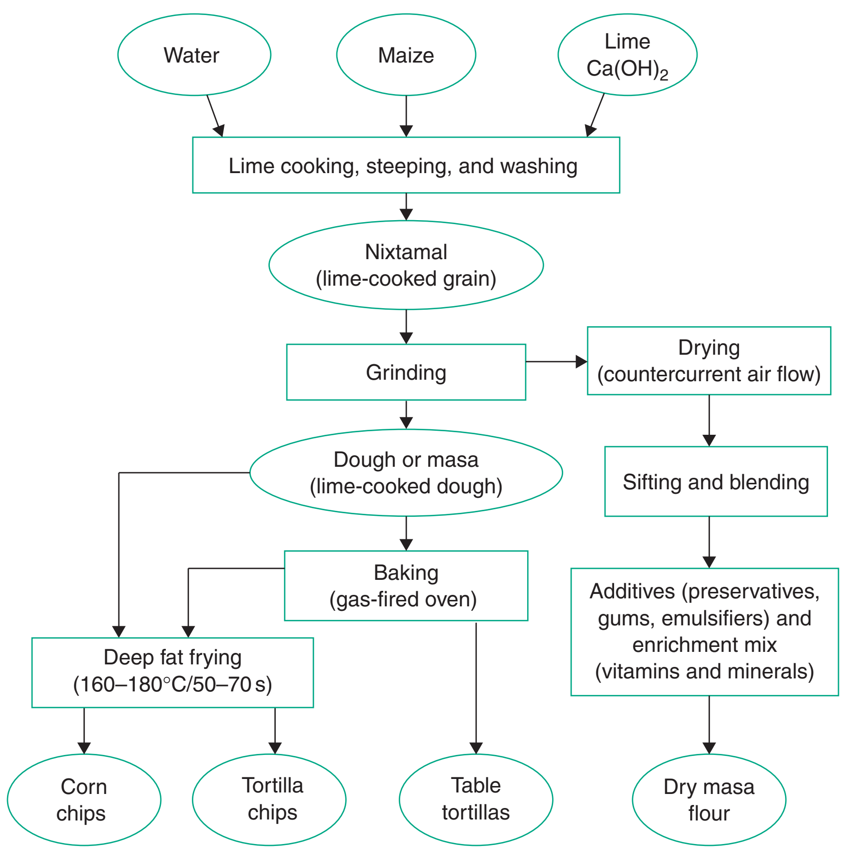

Figure 3 General flowchart for the production of table tortillas, corn chips, tortilla chips, and dry masa flour.

(Table 3). Lime cooking considerably increases calcium and the bioavailability of niacin, and significantly decreases the potential for aflatoxins in contaminated maize.

The industrial production of maize tortillas is labor intensive and requires considerable equipment (*see* **Tortillas**). It starts when the grain is lime-cooked in agitated open baths, vertical cookers, or steam kettles. The grain is generally mixed with 3 parts water and 1% lime, based on grain weight, and cooked for 15–45 min at temperatures ranging from 85°C to 100°C. The nixtamal is then steeped for 8–16 h in the hot lime solution. The cooking liquor is drained and the nixtamal washed with pressurized water. Most of the pericarp and excess lime is removed during this step. The cleaned nixtamal is discharged into a stone grinder, where it is disrupted into a plastic and cohesive dough or masa. Masa is then kneaded by mixers or extruders that feed the forming machine or sheeter rolls. During forming, the masa is rolled into a sheet, which is cut by a rotating cutter positioned underneath the rolls. The formed pieces of masa are fed into a three-tier, gas-fired oven for baking (temperature ranging from 280°C to 302°C for 30–45 s), then cooled through a series of open tiers and packaged. Tortillas are generally treated with gums, emulsifiers, and acidulants and antimycotics (e.g., sorbates and/or propionates) to improve textural and microbial shelf life.

Nixtamalized dry masa flours The use of dry masa flour is rapidly growing because of its convenience. Dry masa flour is produced by drying and grinding lime-cooked, coarsely ground masa (Figure 3). The masa is dried in large dryers in which warm air flows countercurrently to the pieces of masa. A wide array of products can be manufactured by selecting and blending streams with different particle size and color. In most cases, resulting flours are enriched with B-vitamins and trace minerals. Coarser flours with lighter colors are required for snacks. The flour with less than 10% moisture is shelf-stable and only requires water (1.1–1.2 l water per kg flour) to form masa for further processing. Many manufactures use dry masa flour because it does not require much labor, equipment, or space, and processors do not have to worry about effluent disposal and control of scheduling and manufacturing practices.

Fried/snack products Frying has expanded the market for masa-based foods because the final product has excellent organoleptic properties and a long shelf life. The two most popular snacks, tortilla and corn chips, are usually made from coarsely ground fresh masa or masa flours. Corn chips are produced directly from masa (Figure 3) and contain more oil than tortilla chips (Table 3). Tortilla chips are baked similarly to tortillas before frying. Tortillas chips absorb less oil, have a firmer texture, and a stronger corn flavor than corn chips. Nixtamal for these snacks is generally cooked less than for table tortillas, and it is ground into coarse masa, which allows steam to escape through the many small pores during baking and frying. This prevents the formation of serious quality defects, such as oily appearance and blistering. Masa for corn chips is extruded through a die, and cut by rotating knives before frying. Masa for tortilla chips is formed into triangles, strips, or circles before baking, equilibrating, and frying. Frying temperatures and times range from 165°C to 195°C and from 50 to 90 s. Corn and tortilla chips are often salted and flavored immediately after frying. Most popular flavorings include nacho-cheese, hot/spicy, barbecue, lemon-salt, and jalapeño. Special processes to produce baked low-fat tortilla chips that combine air impingement, infrared, and microwaves have been developed.

Pearl

J R N Taylor, University of Pretoria, Pretoria, South Africa

Introduction

Pearl millet, commonly known as bulrush millet (*Pennisetum glaucum* (L.) R. Br.), also classified as *P. typhoides, P. americanum*, or *P. spicatum*, is a cultivated, small-grain, tropical cereal grass. Vernacular names include: "bajra" (India), "gero" (Nigeria, Hausa language), "hegni" (Niger, Djerma language), "sanyo" (Mali), "dukhon" (Sudan, Arabic), and "mahangu" (Namibia). Pearl millet is quantitatively the most important millet, with world annual production ~14 million tons (Mt). It is cultivated mainly in the semiarid tropics, almost exclusively by subsistence and small-scale commercial farmers.

This article will examine pearl millet production and agronomic issues, grain structure, chemistry, and nutritional aspects, primary processing technologies, important foods and beverages produced from pearl millet, pearl millet's future prospects, and research and development challenges.

Production and Agronomic Issues

Pearl millet's great advantage over other cereals is the fact that it can be and is cultivated in areas of very low rainfall (300–500 mm per year) and very high temperatures (day time temperatures above 30°C). Its importance in food security in dry, marginal agricultural areas is immense. It is estimated that some 500 million people in the semiarid tropics depend on pearl millet as a food.

The major areas of pearl millet cultivation are India and northern Africa. It is also cultivated in eastern and southern Africa. In northern Africa there is a broad band of cultivation from Senegal in the west, through Nigeria and Niger to Sudan in the east. Similarly, but on a smaller scale in southern Africa, there is a band of cultivation from Angola and northern Namibia, through Zimbabwe and northern South Africa to Mozambique.

Figures for pearl millet production are only approximate. Some of the available data do not distinguish between the different types of millets and even between millets and sorghum. Also as pearl millet is generally a subsistence crop and not traded, figures are not always available. Pearl millet accounts for about half of the world millet crop, which is ~28 Mt per year. The major pearl millet producing countries are: India ~6.2 Mt per year, Nigeria 4.5 Mt, Niger 1.9 Mt, Burkina Faso 0.8 Mt, Mali 0.7 Mt, and Senegal 0.6 Mt. However, these data belie its importance in some other countries. For example, in Namibia pearl millet is the staple food in the northern, most populous part of the country. The average production is only 65 000 t, but this has to be seen in perspective as Namibia's population is less than 2 million.

Yields are in general very low, on average ~750 kg ha^{-1}. This is because pearl millet is grown in areas of low-rainfall, high-temperature, on light, well-drained soils. Generally traditional farming practices are used with very low inputs, i.e., no biocides or inorganic fertilizers and little application of organic fertilizer, and use of traditional landraces. Pearl millet has, however, much greater potential. In areas where new varieties, some irrigation, and higher input agriculture are used, yields can be well in excess of 2 t ha^{-1}.

Postharvest practices also remain backward in many areas, e.g., manual threshing of the grain (Figure 1). Pearl millet can also suffer severe storage losses, particularly as a result of insects such as the rice moth (*Corcyra cephalonica*). The larvae contaminate the grain by producing webbing (silk) and consume the protein- and fat-rich grain germs. Control is traditionally effected by putting wood ash in the storage bin. Today, application of the fumigant phostoxin (active ingredient phosphine gas) is becoming more widespread.

Grain Structure, Chemical Composition, and Nutritional Value

Grain Structure

Pearl millet grains are tear shaped to ovoid (Figure 2). They are up to 2 mm in length and the 1000 kernel weight is in the range 3–15 g (typically ~8 g), about one-quarter that of a wheat grain. The overall grain color varies from pearly white (hence the name) to yellow, slate gray, brown, or purple. Individual grains are often not uniformly colored.

The general grain structure is essentially the same as the other major tropical cereals, maize and sorghum (Figure 3). The kernel is naked, i.e., it generally threshes free of the hull. A feature characterizing pearl millet grain structure is the proportionally very large germ, and hence relatively smaller endosperm. This impacts on the chemical composition of the grain. The endosperm comprises two major components: the outer corneous (also referred to as vitreous or hard) endosperm and the inner floury (also referred to a soft) endosperm. The cells of the corneous endosperm are filled with a continuous matrix, without airspaces of proteins comprising protein bodies and matrix protein. It contains few starch granules. In contrast, the cells of the floury endosperm have airspaces in them and contain relatively many more starch granules and less protein. The pericarp is variable in thickness, dependent on variety, and comprised of three layers: the epicarp, mesocarp, and endocarp. The mesocarp apparently may contain starch granules such as sorghum grain. Beneath the pericarp is a seedcoat, which may be pigmented and beneath this is the aleurone layer, part of the endosperm, which is one cell thick. The kernel is enveloped in a waxy cutin layer, which protects the grain against weathering.

Chemical Composition and Nutritional Value

The general chemical composition and major nutrient contents of pearl millet grain are given in Table 1. It should be noted that these values refer to the whole, unprocessed grain. Processing by milling and malting will affect both the content and availability of many nutrients.

Figure 1 Manual threshing of pearl millet in northern Namibia.

Energy Whole pearl millet grain has a high energy content, in the range ~1646–1691 kJ per 100 g dry basis (db), compared to all other cereal grains except maize. This is due to the high fat content of these two grains.

Carbohydrates As with all other cereals, the predominant carbohydrate in pearl millet is starch. The starch content, typically ~71–72% (db), is perhaps slightly lower than most other cereals, due to the fact that the germ of pearl millet grain is large and hence the endosperm is smaller. The percentage amylose in pearl millet starch is in the range ~17.0–21.5%, which is relatively low for normal starches. However, waxy, 100% amylopectin (amylose-free) pearl millet mutants have not been found as yet. The starch gelatinization temperature is in the range 61–69°C, typical of tropical cereal starches.

Soluble sugars in pearl millet grain, as in all sound cereal grains, are low, in the range ~1.4–2.8%, with the major sugars being sucrose and raffinose.

The dietary fiber content of pearl millet grain, ~8–9% (db), surprisingly appears to be lower than most

other cereals, despite the fact that the grain is relatively small. This should mean that the proportion of bran is higher. However, this dietary fiber value may be an underestimate since dietary fiber determination is notoriously complex. The dietary fiber of pearl millet, as with sorghum, is mainly of the insoluble (water-unextractable) type. Thus, it has benefits in terms of preventing constipation, but probably does not have the cholesterol lowering effect of soluble fiber.

Proteins and amino acids Pearl millet grain protein content, typically 14.5% (db), is high for cereal grains. This is because the grain has a large germ. This, in turn, also affects the balance of Osborne protein groups and the overall amino acid composition of the pearl millet protein. Considering the protein fractions, the prolamins (aqueous alcohol soluble) proteins, 31–41% of total protein, are as in most other cereals the major fraction in pearl millet. However, this level is lower than most other cereals as prolamins are endosperm-specific proteins. In contrast, the amount of albumins and globulins (saline soluble) proteins, 25–26% of total proteins, is probably somewhat higher than in most other cereals.

Concerning the prolamin proteins themselves, in pearl millet they are called pennisetins and are similar to the prolamins of maize and sorghum, with high contents of glutamate+glutamine (23–24 wt.%), alanine (8–9 wt.%), and leucine (~14 wt.%), but relatively low in proline (~8 wt.%) and cystine and methionine (~1 wt.% each). Sodium dodecyl sulfate polyacrylamide gel electrophoresis under reducing conditions shows a major band of $M_r \sim 22$ kDa and minor bands of $M_r \sim 20$ and 10 kDa. Research indicates that, unlike the situation with sorghum, wet cooking, as occurs in porridge making, does not reduce the digestibility of pearl millet protein. The reason for this is not known, since the reduction in sorghum protein digestibility is believed to be due to cross-linking of the prolamin proteins, which, as stated, are very similar to those in pearl millet.

The amino acid composition of pearl millet protein (Table 1) is characterized by a relatively high content (compared to most cereal grains) of the essential amino acid lysine, in the range 2.8–3.2 g per 16 g N. This is on account of the relatively high proportion of lysine-rich albumin and globulins, due to pearl millet's large germ. However, the lysine content of pearl millet by no means meets the requirements of infants (or for that matter school age children), although it is satisfactory for adults. This emphasizes the importance of supplementation of cereals in the diet with meat, dairy, or legumes, as sources of lysine. Pearl millet protein is, as shown, a satisfactory source of the other essential amino acids.

Fats The fat content of pearl millet grain, typically 5.1% (db), is high compared to all other cereal grains, except maize. In the case of both pearl millet and maize the high fat content is due to the large germ. As with all other cereals, the major fatty acids are linoleic acid (C18:2), typically 43–45% of the total, oleic acid (C18:1), 26–27% of the total, and palmitic acid (C16:0) 20–21% of the total. The high content of fat and in particular of polyunsaturated fatty acids means that whole grain pearl millet when milled is highly subject to deterioration through oxidative rancidity.

Vitamins Pearl millet, like other cereal grains, is an important source of vitamin B (Table 1). These are concentrated in the aleurone layer and germ. Hence, their content can be adversely affected by milling. Niacin occurs partially bound to carbohydrate. To make it fully available, the flour has to be treated with alkali. This is done by treatment with wood ash in the preparation of the West African porridge called "tô." Because of its high fat content, pearl millet is a good source of tocopherols (Vitamin E), located mainly in the germ.

Minerals Pearl millet grain, like other grains, is a good source of most dietary minerals (Table 1), with the exception of calcium. Quantitatively the highest contents are of phosphorus and potassium. However, the availability of the former and of the multivalent metal ions is negatively affected by the presence of phytate (see below). The minerals are concentrated in the pericarp, aleurone layer, and germ. Hence, their content can be adversely affected by milling.

Antinutrients

There is evidence that pearl millet contains goitrogens. It appears that the goitrogens are primarily phenolic flavonoid-type compounds, the C-glycosyl flavones: vitexin, glucosyl vitexin, and glucosyl orientin. Other phenolic compounds, such as phloroglucinol, resorcinol, and p-hydroxybenzoic acid, could also be involved. These compounds apparently inhibit the deiodination of the hormone thyroxine to its more active form triiodothyronine. They are concentrated in the outer layers of the grain and are considerably reduced when the grain is de-hulled during milling. In fact, the nutritional significance of the goitrogens in pearl millet should not be overstated. Although some rural people, e.g., in the Sudan, who consume pearl millet as a staple have been found to suffer from goiter, it is probable that this is because their diet is very restricted and hence deficient in iodine.

The C-glycosyl flavones contribute to the brown/gray color of pearl millet and also appear to be responsible for the characteristic musty flavor of damp pearl millet flour, which is probably of greater nutritional significance. Some people describe the flavor as being "mousy" or "mouse-dropping" like. In pearl millet foods, such as porridges, it can be rather disagreeable to those not familiar with the food.

Pearl millet, like all grains, contains the phosphorus-containing compound phytate, myo-inositol hexaphosphate. Phytate is believed to act as the main phosphorus store in seeds. In grain foods, it has the undesirable property of binding multivalent metal cations such as iron and calcium and rendering them biologically unavailable. The level of phytate in pearl millet grain, in the range ~172–327 mg per 100 g, is typical of cereal grains. Phytate in pearl millet, as in other cereal grains, is located in the aleurone layer and germ. Hence, de-hulling the grain during milling substantially reduces the level of phytate (but also the minerals) in flour. Malting specifically reduces the level of phytate by enzymatically degrading it, freeing the minerals.

It should be noted that contrary to what is written in some texts, pearl millet, unlike some varieties of sorghum, does not contain the antinutritional polyphenolic compounds, condensed tannins.

Primary Processing

Milling

Pearl millet is milled into flour for porridge and bread making. The milling process used in northern Namibia is shown in Figure 4 and will be described in detail as it has some unique features.

De-hulling To improve the palatability and storage quality of the flour, the bran (pericarp and germ) is generally removed from the grain first. This process of bran removal is referred to as de-hulling. Strictly speaking, decortication is the correct term since the pearl millet grain does not have a hull.

Figure 5 shows the equipment used in a small-scale commercial pearl millet mill in Namibia. In the background is a Prairie Research Laboratory (PRL) de-huller, named after the place where this equipment was first developed. Today, PRL-type de-hullers are manufactured in a number of countries in southern Africa. The PRL de-huller comprises an axle with ~12 carborundum disks mounted on it, within a cylindrical box. The axle revolves at high speed and the disks abrade off the bran from the grain. A suction fan removes the bran. The amount of de-hulling is determined by the duration of the de-hulling process. Anything between 10% and 30% of the grain is removed, depending on the desired final color and fat content of the flour. De-hulling has the effect of reducing the fiber, fat, and protein content of the grain due to removal of pericarp and germ material. The quality of the protein will also be adversely affected as the quantity of the lysine-rich germ proteins is reduced. The starch content is increased slightly.

Steeping The de-hulled grain is steeped in ambient temperature water overnight. This steeping process is

actually a lactic acid fermentation. A lactic acid bacteria "culture," maintained by the process of "back-slopping," is used to inoculate the steep water. The culture comprises a portion of the previous steep, which has developed a strong, clean acidic taste due to a high load of suitable lactic acid bacteria. The purpose of the lactic acid steep seems to be several fold. It lightens and brightens the flour. The low pH of the steep water is responsible for lightening the color and partially leaching out the brown/gray polyphenolic pigments of the grain. Goitrogens may also be leached out of the grain. However, it is probable that water-soluble proteins, vitamins, and minerals are lost in the steeping process. The steep softens the grain, facilitating its reduction into a fine flour. The resulting flour has an acidic flavor, which consumers prefer.

Solar drying The de-hulled, steeped grain is partially dried before milling, and after milling the flour must be fully dried to a shelf-stable moisture content of ~10%. Solar drying is used for both steps. The grain or flour is dried on polythene sheets, either outdoors or under cover, on either directly on a concrete floor or on long tables made of wooden slats.

Milling The partially dried, de-hulled steeped grain is milled into a fine flour using a powerful hammer mill, fitted with an ~1 mm screen. The hammer mill has to be powerful on account of the high moisture content (30–40%) of the grain. Thus, the process is actually semiwet milling. This apparently rather inefficient process seems to be necessary in order to mill the grain into a suitably fine flour.

Malting

In sub-Saharan Africa, pearl millet is malted to produce malt for brewing traditional opaque beer and

Figure 6 Pearl millet malt before drying. (Courtesy of L A M Pelembe.)

nonalcoholic beverages. Pearl millet malting is almost exclusively done in the home, although one large-scale commercial malting in Zimbabwe malts pearl millet together with sorghum. Figure 6 shows pearl millet malt prior to drying. It can be seen that there is extensive root and shoot growth. The optimum temperature conditions of pearl millet malting are in the range 24–28°C, identical to that for sorghum. The malting process involves three steps: steeping, germination, and drying.

The steeping time for pearl millet is short, up to 8 h, as the grain germinates rapidly. Germination is for 4–5 days. Like sorghum, pearl millet must be watered during germination. Drying is at ambient temperature or up to 50°C in order to conserve malt enzyme activity.

The pearl millet malt quality seems to be somewhat higher than that of sorghum malt. Diastatic power (total amylase activity) is similar, ~30–50 sorghum diastatic units (SDU) g^{-1}. However, the activity of the β-amylase component is higher. β-Amylase is the enzyme that produces the fermentable sugar maltose. The higher β-amylase activity indicates that pearl millet malt could have potential as partial substitute for barley malt for brewing lager beer. Free amino nitrogen and extract are also higher in pearl millet malt than sorghum malt. Of particular significance is the fact that malting almost completely eliminates the mousy flavor associated with pearl millet flour. Some nutritional improvements also occur, in particular improvement in carbohydrate and protein availability. However, against this there is a substantial overall loss in mass of grain, 10–15%, due to respiration during germination.

Food and Beverage Production

Worldwide, pearl millet is processed into many different food and beverages. Foods include: "rice" and flatbreads ("roti") in India, "couscous" in Mali and Senegal, thick porridge such as "to" in West Africa and "bogobe" in southern Africa, and thin fermented porridges ("uji") in eastern Africa, respectively. Beverages can be nonalcoholic like "oshikundu" in Namibia or alcoholic like the opaque beer of southern Africa.

Foods

Porridge In sub-Saharan Africa, pearl millet is often consumed as a porridge. A traditional Pedi (Limpopo Province, South Africa) recipe to make "bogobe bia bupi bja leotsa" (literally porridge of pearl millet) involves cooking ~1 kg of whole grain pearl millet meal in 1.9 l water. The porridge has greenish-brown

color, and a thick, smooth viscous consistency. Because of the high ratio of starch to water the porridge gels on cooling. The flavor is musty, sweet, and bitter. The meal ration size is ~1 kg, which provides some 525 kJ, 20–25% of an adult's "recommended dietary allowance." The porridge is traditionally eaten cool or cold with the hand. It is served with vegetable relish.

Flatbread In India, pearl millet is generally consumed as a crisp flatbread, called roti or "chapati." Figure 7 shows a flowchart for making roti. A problem in making breads from nongluten containing grains such as pearl millet is that the product tends to break into pieces. It is notable that in the milling process the flour is ground to fine particle size, ~43% having a particle size <75 μm. This increases the surface area of the flour particles and damages the starch granules, increasing their water absorption. Both factors increase the cohesiveness of the dough. Variations on the roti-making process which also alleviate the problem can involve cooking part of the flour in water and mixing it together with the uncooked flour. Cooking gelatinizes the starch making it into a binder which improves the cohesiveness and elasticity of the dough. Alternatively, pearl millet flour can be composited with flours that give better cohesiveness such as legume flours or wheat flour which gives elasticity.

Because of the absence of gluten in pearl millet, breads made from pearl millet flour are unleavened. However, in the roti-making process, as shown in Figure 7, the flatbread is exposed on one side to high heat, which puffs it giving the bread some "leavened" texture. Puffing takes place as result of the fact that the moistening water added during baking is very rapidly turned into steam. The resulting increase in volume creates an air sac as the steam escapes.

Roti is served with a small amount of hot pickle, "dhal," or vegetable sauce.

Beverages

Throughout Africa, sorghum, maize, and millets are used to produce nonalcoholic and alcoholic beverages. Invariably, these beverages have undergone a lactic acid fermentation, giving them a refreshing sour taste. The low pH of the beverages renders them free from food-borne pathogenic bacteria and helps protect them against microbial spoilage.

Nonalcoholic A very popular nonalcoholic fermented beverage in Namibia is oshikundu made from pearl millet and sorghum malt flour. Some 200 g of pearl millet flour are thoroughly mixed into 500 ml of boiling water. Then ~100 g of sorghum malt flour is added. Sorghum malt provides amylase enzymes and lactic acid bacteria. α-Amylase thins the porridge into gruel by hydrolyzing the starch into dextrins and β-amylase further hydrolyzes the dextrins into maltose. The thinning and hydrolysis actions of the amylases improve food palatability and carbohydrate availability. The lactic acid bacteria use the maltose and other fermentable sugars for respiration, producing lactic acid and other flavor compounds. After the mixture has cooled to room temperature, 1–1.5 l of cold water is mixed in. The container is closed and the mixture is allowed to ferment overnight before consumption. Oshikundu is greenish brown in color and has the consistency of drinking yogurt. It is slightly effervescent with a buttery sour taste. A lactic acid content of 0.6% has been measured.

Opaque beer In several southern African countries pearl millet malt is used to brew traditional, opaque-type beer. Figure 8 shows a flowchart for a Pedi recipe for making "bjalwa bja leotsa" (literally beer of pearl millet). The process has some interesting

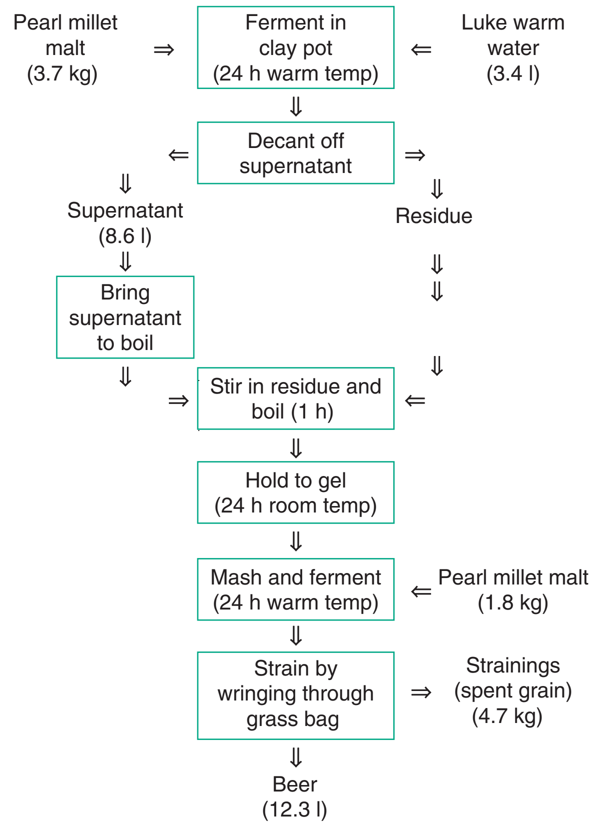

Figure 8 Pearl millet opaque beer-making process.

features. It is noteworthy that only malt is used in the recipe. In contrast to brewing traditional sorghum beer, no unmalted grain adjunct is used. In fact, part of the malt is used as adjunct by cooking it after the first fermentation process. The first fermentation process is probably primarily a lactic acid fermentation but some fermentable sugar production will also take place. As there is no unmalted adjunct in the recipe, it means that there is a proportionally higher ratio of amylase enzymes to starch, producing more fermentable sugars. Coupled with the fact that pearl millet malt intrinsically contains a higher ratio of β-amylase, this probably accounts for the fact the pearl millet beer is claimed to be more intoxicating than sorghum beer. Typical of traditional recipes more than one process takes place during a particular step. This is unlike modern food and beverage manufacturing processes where there is a system of unit operations. In the mashing and fermentation stage, gelatinized starch is hydrolyzed by the malt amylase enzymes into fermentable sugars, which are fermented by both yeast and lactic acid bacteria to produce ethanol, carbon dioxide, and lactic acid as the main products. The beer is described as turbid, greenish-brown in color, with a milk-like consistency. The flavor is musty and bitter sour, with a lactic acid content of ~1.8%. Pearl millet beer could be much thinner and more acidic than sorghum beer.

Future Prospects and Challenges

With the world faced by the threat of global warming and its resulting climatic changes, pearl millet with its unique ability to grow under hot and dry conditions should become a far more globally important food grain. In the developing world the need for food security demands that pearl millet increasingly becomes a commercially traded grain and is processed into food products, instead of just being a subsistence crop.

ICRISAT, the International Crops Research Institute for the Semi Arid Tropics, has helped develop pearl millet varieties with improved agronomic and processing qualities. In Namibia, for example, the "Okashana" improved varieties that are early maturing, higher yielding, and large grained have found wide acceptance among farmers, resulting a substantially increased pearl millet crop. This has resulted in a surplus over and above immediate household requirements, which is available for trade and processing. In turn, this has led to the growth of small-scale commercial milling operations, as shown in Figure 5.

Such developments can, however, only take place if governments create an enabling environment. In Namibia, the Ministry of Higher Education, with the assistance of the Food and Agriculture Organization of the United Nations (FAO), is implementing a very interesting local project for the development and promotion of new pearl millet products. In 2002, the Council for Scientific and Industrial Research in South Africa produced sample quantities of a range of concept products, such as instant porridges and snack foods. These were consumers evaluated in Namibia to determine the preferred concept products. At the same time a pearl millet food product manufacturing training facility has been constructed in northern Namibia. Food technologists at the facility will train entrepreneurs to manufacture these products. This project could serve as a model for other millet and sorghum-producing countries to follow.

Pearl millet scientific and technological problems still requiring further research and development include: finding a more efficient way of milling the grain to reduce losses, elimination of the "mousy aroma" in pearl millet foods, and determining whether there is really a significant goitrogen problem.

Millet is a generic term implying "small seeded grain;" thus the variations in millet are quite large. The millets are all within the grass family (Poaceae or Gramineae), but include two tribes, Paniceae and Chlorideae (Table 1). The most widely grown millets include pearl millet (*Pennisetum glaucum*), proso millet (*Panicum miliaceum*), and foxtail millet (*Setaria italica*). However, smaller areas have meaningful production of brown top millet (*Brachiaria ramosum*), Japanese (*Echinocloa frumentaceae*), Shama (*Echinocloa colonum*), Australian (*Echinocloa decompositum*), and barnyard millet (*Echinocloa frumentaceae*). Finger millet *(Eleusine coracana*) is the most economically important member of the Chlorideae tribe, but teff (*Eragrostis tef*) plays a major role in Ethiopia. Black and white fonio millet (*Digitaria iburua* and *Digitaria exilis*, respectively), while grown in limited areas, are known for their good taste, short growing season and ability to produce on very poor soils. The variation represented by millets as a group, ranges from plants that grow to well over 4 m in height and take more than 150 days to reach maturity, to plants that seldom reach a height of more than 1 m and mature in less than 75 days. Production of millets can be found from the tropics, with rainfall averaging over 1200 mm per year, to the steppes of Siberia with rainfall averaging less than 300 mm. While all millets can be classified as cereals, in that they are grown for their edible starchy seeds, many are also important for annual forage production. Primary uses for millet grain vary as much as the species themselves, but include various forms of porridge for human consumption.

Millet Importance and Production Areas

According to 2002 FAO reports, millet ranks fifteenth among all crops in terms of calories produced for human consumption. Of the minor millets, foxtail, proso, and finger millet account for the bulk of this production, but teff and fonio millets are regionally important. For example, a high portion of the cereal production of Ethiopia is dedicated to teff, and in West Africa, fonio is extremely important for the highly degraded soils (*see* **Teff**). Little millet (*Panicum miliare* or *sumatrense*) and kodo millet (*Paspalum scrobiculatum*) are primarily restricted to limited production in India and appear to be related to proso millet. Brown top millet (*Brachiaria ramosum*) has been used to a limited extent in India, but has played a role in the southeastern US as a cover crop and for wild bird hunting areas. Millet production data are elusive and frequently confusing because these sometimes include sorghum and the figures from subsistence agriculture production regions are often crude estimates. However, the total millet production probably provides a primary calorie source for more than 500 million people in the world. The bulk of this production is in China and India, with the next largest areas including West Africa and the former Soviet Union.

Table 1 Classification of millets, family Poaceae

Tribe	*Genus*	*Species*	*Common names*	*Potential center of origin*
Chlorideae	*Eleusine*	*coracana* (L.) Gaertn	Finger millet	Africa
Paniceae	*Brachiaria*	*ramosum* (L.) Stapf	Brown top millet	Africa
	Digitaria	*exilis* (Kipp.) Stapf	Fonio millet	Africa
	Echinocloa	*colona* (L.) Link	Shama millet	India
		frumentacea Link	Japanese, barnyard millet	China
	Panicum	*miliaceum* L.	Proso, common, hog millet	China
		miliare Lam.	Little millet	India
	Paspalum	*scrobiculatum* L.	Kodo, ditch millet	India
	Pennisetum	*glaucum* R. Br.	Pearl millet	Africa
	Setaria	*italica* (L.) P. Beauv.	Foxtail, Italian millet	China

Adapted from Rachie KO (1975) *The Millets Importance, Utilization and Outlook*. Hyderabad, India: International Crops Research Institute for the Semi-Arid Tropics.

Millet Biology

Millets initially develop from seminal roots. These roots arise directly from the hypocotyl of the seedling. Further plant growth includes the development of a second set of roots, called the adventitious or crown roots, which form at a point on the plant just below the surface of the ground called the crown. Millet roots are characteristically fibrous rather than tap rooted like alfalfa or sunflower. Soil erosion is a limited problem with millet production because of this root system.

Alternate two-ranked leaves are the identifying characteristic of cereals in general, but the millets are differentiated, by most taxonomists primarily, on the basis of their inflorescence. The stems are composed of nodes and internodes which elongate to varying degrees as the crop matures. The lower nodes on a plant have the potential to develop additional stems, which are referred to as tillers. Millets have wide variation in their ability to tiller, and the ability to regrow when harvested as forage. This is a primary selection criteria once a particular end use is determined.

Millet seeds (correctly described as caryopses) are composed of three main parts, the endosperm, embryo (germ), and seedcoat (pericarp). Starch is the primary constituent of the whole grain, but is especially concentrated in the endosperm. Protein is found primarily in the embryo and to a lesser extent in the rest of the seed. Most of the oil is located in the embryo as well. The seedcoat consists mainly of cellulose and hemicellulose. Typical crude protein levels for the millets average $\sim$12% on a dry matter basis.

Proso

Proso is the most widely grown millet grain crop in the US. It is well adapted to short-season production with both quick maturity and a low water requirement. It is more cold-tolerant than either foxtail or pearl millet. Proso is considered a short-day plant and most US plantings are of an upright growth type with a relatively dense head compared with wild types. Recent studies suggest that proso plant development and maturity are heat-unit-driven across a wide range of day lengths.

Proso is considered to be diploid by some, but $2n = 4x = 36$ is a more appropriate discussion. While pairing is relatively normal during cell division, many alleles follow a tetraploid inheritance pattern. Self-pollination dominates in proso, but natural cross-pollination may exceed 10%. Proso seeds are smaller than grain sorghum (*Sorghum bicolor* L.), generally oval in shape and about 3 mm long and 2 mm wide. Seed size selection has led to an increase in seed size in popular varieties along with most varieties being a light cream color (referred to as white proso). Some niche markets exists for red types and the germplasm base covers the breadth of seed colors. Little millet may be related closely enough to proso millet to be used as a germplasm source, but carries few traits of known economic importance, being smaller seeded and less productive.

Most proso is swathed prior to harvest, allowed to dry and then combined. Selection has decreased seed shatter loss and increased uniformity of maturity so that increasing areas are harvested each year directly. Stripper headers and combines, better able to separate the green plant parts from the seed have, also helped to increase the amount of direct harvested proso millet. More primitive harvest techniques are still utilized in regions where proso is grown as a subsistence crop.

Pearl Millet

Pearl millet (*see* **Millet**: Pearl) breeding has led to the development of some grain type hybrids adapted to US conditions, but most of the pearl millet produced in the

Table 2 Main uses of different millets

Millets	*Food use*	*Feed use*	*Other use*
Proso millet	Steamed buns, cake, dumpling, oil pudding, sour meal, and popping food (Chinese traditional millet foods), snack foods	Pet and livestock feed	Therapeutic/healthy use, brewing Chinese white or yellow millet wines and vinegar
Foxtail millet	Thin or thick porridges (*sargati*, *sankati*, etc.), boiled rice-like products, snack foods	Forage or grain feed	Therapeutic/healthy use, brewing material of Chinese five-grain vinegar
Finger millet	Porridges or sweet gruel, "chapati" and "soda" (Indian unfermented and fermented breads), popping meal, snack foods, sweetmeats, weaning foods	Animal feed	Brewing traditional African beer
Teff	Porridges, fermented flat bread (e.g., "injera" in Ethiopia and "kisra" in Sudan), unleavened flat bread ("kitta" in Ethiopia), cookies, muffins, waffles, soups, and pudding in Ethiopia	Forage or grain feed	
Fonio	Porridge, composite flour bread, popping food	Forage or grain feed	Brewing African local beer
Barnyard/Japanese millet	Rice substitute, Japanese traditional food		
Kodo millet	Food uses are the same as for foxtail millet in India

US is for forage production. This is in stark contrast to areas of Africa where it is a primary grain crop. Pearl millet is adapted to more acid soils, higher temperatures, and higher humidity than proso. It is more susceptible to injury by cold temperatures and most genotypes have a relatively long growing season compared to proso.

Foxtail

Foxtail (*Setaria italica*) is one of the world's oldest cultivated crops. Foxtail was the most important plant food in the neolithic culture in China, and its domestication and cultivation was the earliest identifiable manifestation of this culture. The US patent office introduced foxtail millet as a forage crop in 1849. It has since become well adapted to the western Great Plains. Nearly all foxtail millet cultivars grown in the US are the result of selections from land races rather than designed crosses and selections. Foxtail is recognized as a diploid ($2n = 2x = 18$), but is closely related to many tetraploid and higher ploidy level species.

Foxtail millet grown in the US is typically less than 1.5 m in height with a stem intermediate in size between proso and pearl millet. Head length is variable like pearl millet, but shorter and more lax. Foxtail is self-pollinated for the most part and, with a compact panicle and small florets, it is extremely difficult to cross. Improved techniques have been developed by Melicio Siles and others, but limited directed genetic improvement has been made due to this constraint.

Finger, Teff, and Browntop

Finger millet (*Eleusine coracana*) and browntop millet (*Brachiaria ramosum*) have been utilized on a small regional basis and have characteristics that offer potential for further development. Browntop is grown in the southeastern US primarily as a cover crop and for wild game feed. Finger millet has been explored as a grazing and forage crop, but is currently used on only a limited basis.

Millet Uses

Table 2 summarizes major uses of different millets. Millets have long been utilized as traditional staple foods for a large amount of the world's poor, especially in Asia and Africa. Currently, millets are consumed in northern China, India, Africa, and southern Russia, with ~80% of the world's millet production directly consumed as human food. Other utilization of

millets includes brewing use, therapeutic or health-food use, feed use (bird feed, livestock feed, forage, etc.), and mushroom production. Different millets have been used to process numerous food products, such as thick or thin porridges, steamed food products, cakes, fermented and unfermented breads, snacks, weaning foods, and alcoholic and nonalcoholic beverages, etc. These millet foods originated from various places of the world with unique local flavors and rich nutritional profiles. Moreover, there are differences in the details of recipes and preparation for each kind of millet-based food between communities and regions in different countries. Frequently, the same millet food may have several different names because of language and custom differences.

Foxtail millet is the most widely grown millet in China and millions of people depend on it as a primary calorie source. It is grown, to a lesser extent, in India, and throughout Europe and Asia.

In northern China, minor crops including millets and their specialty foods are preferred. Major millets in China include proso millet, foxtail millet, and finger millet. There are many local traditional foods made from proso millet and foxtail millet with a long history and special flavor, such as proso millet oil pudding, sour meal, steaming buns, sweet cakes, pyramid-shaped dumpling, foxtail millet porridge, cooked rice-like foods, etc. These traditional millet foods have been and are still popular throughout the rural areas and towns of northern China and also in many major cities of northern China (especially in Shanxi, Shaaxi, Ninxia, Inner Mongolia, and Gansu). Popped yellow millet grains are used as a major component of local milk tea or butter tea (famous in Inner Mongolia). Waxy proso millet has been used to brew local white millet wine and yellow millet wine in various regions of northern China for ~2000 years. Millet grains are the brewing material base of Chinese five-grain vinegar (rice, buckwheat, millet, sorghum, and mungbean). Proso production is very important in China and the former Soviet Union, but is also used in Eastern Europe, the Middle East, India, and Southeast Asia.

India and some African countries (Nigeria, Niger, Sudan, Ethiopia, etc.) are important areas of world millet production. In India, most millets (e.g., proso millet, finger millet, barnyard millet, kodo millet, little millet, foxtail millet, etc.) are used for many kinds of foods, including porridges, boiled rice-like products, steam-cooked products, baking foods, snacks, weaning foods, composite flours mixed with other cereals, and pulses for making common foods. In Africa, many millets (e.g., pearl millet, teff, finger millet, fonio, etc.) are consumed in the form of thick and thin porridges, fermented or unfermented flat breads, steamed or boiled cooked millet foods, snacks, and composite flours mixed with other cereals for breads, cookies, noodles, etc.

In India and Africa, millets are used or mixed with other cereals to make different local traditional foods. For example, pearl millet and finger millet are used to prepare "chapati" or "roti" (unfermented bread) and "soda" (fermented bread) in India and "ndaleyi" (local traditional food) in Nigeria. In Sudan and Ethiopia, fermented flat breads ("kisra" and "injera") can be prepared using both pearl millet and teff. Unleavened flat bread ("kitta") are made using teff in Ethiopia. These breads can be eaten in different ways for breakfast, lunch, and dinner. Also, they can be consumed with vegetables, sauces, milk, meat, curd, etc. Foxtail millet is used to make "sargati" (porridge) and pearl millet is blended with baobab flour to prepare "bulum mardam" (gruel) in India. Teff is employed to prepare "genfo" (stiff porridge) and "atmit" (thin porridge/gruel) in central Ethiopia. Additionally, pearl millet, fonio, and finger millet are usually used or mixed with other cereals to brew traditional African alcoholic and nonalcoholic beverages with different local flavors, such as "chibuku" in Zimbabwe, "tchapalo" in Togo and "burujuto" or "pito" in Nigeria. Malting and brewing local beers using millets is significant in many countries of Africa, especially in eastern and southern Africa. Nonalcoholic beverages are also made from millets in West Africa.

Proso is produced throughout the central and northern Great Plains of the US with more than 170 000 ha produced annually. Nebraska, Colorado, North Dakota, South Dakota, Kansas, Wyoming, and Minnesota account for more than 90% of all proso production. Proso is the primary millet traded across national borders and most world trade figures for millet consist primarily of proso.

Interestingly, millets can be used for therapeutic purposes. Most millets are highly nutritious, for example, rich in protein, lipid, vitamins, and minerals compared to some other cereals. They also have a unique balance of amino acids that complements other cereals. In China and Japan, some food products made from proso millet, foxtail millet, and Japanese millet are considered to be functional or therapeutic foods to prevent and reduce incidence of certain human diseases. Regularly eating millets as a dietary and nutritional component in foods can reduce incidence of chronic human diseases. It is said that regularly drinking Chinese millet wine may improve human health, and yellow millet wine made in Shandong and Shanxi provinces of China is used for recovery of malaria patients. Special local millet foods (e.g., millet sour meal or porridges) are helpful in case of sunstroke. Japanese barnyard millet grains have

been used as basic food materials for patients with allergic disease, including atopic dermatitis in Japan. Also, African, Indian, and Russian reports indicated that millets have a higher glycemic index than wheat breads, rice, potato, maize, and cassava. Russian millet is promising for use by diabetics because of moderating influence on blood glucose level. It has been observed that millet consumption is related to a lower incidence of pellagra (a niacin-deficiency disease).

Also, millet grains are commonly used as feed for pets and other animals. It is also extensively used for poultry feed and to a more limited extent as feed for other livestock. US proso is primarily consumed by the birdseed market, but poultry and other livestock are also major users. Human consumption, while prevalent elsewhere, accounts for a small proportion of US production. Foxtail millet has been playing an increasingly large role in wild bird feeding mixes in developed countries.

Many reports have shown that animals fed pearl millet, finger millet, proso millet, and foxtail millet grains generally had better performance in body-weight and body-condition scores than those fed corn or sorghum. It has been particularly valuable in the poultry industry. Since millet usually has a premium price for human use and the bird seed trade, it typically only finds its way to livestock rations in years of excess production. Extensive research supports the use of all millet grains as livestock feed from a nutritional standpoint, but corn is frequently less costly.

One of the largest uses for millets is as forage. When green forage is harvested at plant heading up to the initiation of grain fill, the quality for livestock is excellent. With most millets, total energy per unit land area is maximized around heading. The millets are harvested for hay, green chop, silage, or grazed directly. Foxtail and pearl millet are primarily used as forages in the US, with foxtail millet being preferred as a hay crop and pearl millet preferred for grazing, but proso millet is also used as an emergency hay crop. Foxtail is easier to harvest for hay than pearl millet due to finer stems that cut and dry more readily. Under marginal conditions, due to limited rain or short growing season, it becomes the hay crop of choice. It is not as readily utilized for grazing with limited regrowth and a tendency to be pulled up by grazing animals. It is typically more productive as a forage than proso varieties, but has similar uses. Protein and energy values for millets have a very wide range with maturity and growing conditions, but protein levels of 12–15% with TDN levels greater than 65% are common when hay is put up at the heading stage of plant development. Crop residues or straw of proso, teff, fonio, finger millet, and foxtail millet are fed to livestock, and are considered to be valuable forage with protein and energy levels higher than wheat or rice straw.

Millet Processing and Development

Because millets are still a “poor man’s crop” in the developing countries, both milling and food processing of millets are considered to be mainly at traditional, manual, or household levels without industrial standardization compared to other important cereals. However, some small-scale mechanical operations have been used in modern millet food processing.

Traditional milling methods, while labor-intensive and time-consuming, are still widely used in many developing countries. Millet grains are usually decorticated and ground with mortar and pestle or stone grinders by hand. Millet grains have been decorticated with mechanical de-hulling equipment and ground into flour with similar mechanical attrition or hammer mills in some villages and urban areas in India, northern China, and some African countries. Milling time and flour yields are normally dependent on millet grain size, shape, hardness, and thickness of pericarp. It is also reported that modern milling equipment for wheat flour has been used for milling proso millet into flour.

Currently, most traditional millet foods are handmade. Germination (malting) and fermentation are major processing steps of millets, widely used for production of traditional millet foods. Malted and fermented millets (e.g., pearl millet, proso millet, finger millet, fonio, teff) can be used in the preparation of porridges, flat breads, and weaning foods and in the brewing of various traditional African beers and Chinese traditional millet wines. For instance, injera is a traditional Ethiopian fermented flat bread. Teff is considered to produce injera with better quality than sorghum. Figure 1 describes details of traditional processing procedures of injera made from teff. African opaque beer is brewed from sorghum and/or millets. The opaque beer production takes ~5–7 days, depending on ambient temperature. Its processing procedure mainly includes grain malting, souring (lactic acid fermentation), cooking, mashing, straining, and alcoholic fermentation. The important stages are lactic acid fermentation, mashing, and alcoholic fermentation. African opaque beer usually has high levels of suspended solids, and has a sour taste and light pink color.

Most common, of the many hand-made traditional millet foods in China, are the various types of foxtail millet porridges. Proso millet oil pudding is a famous local traditional food in Shanxi province. Detail of its

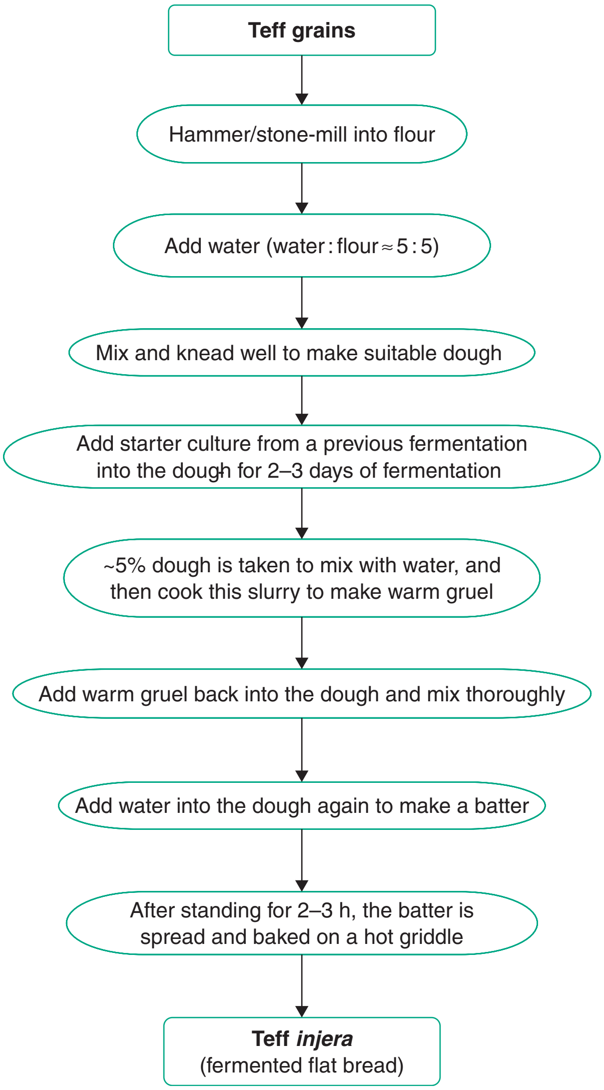

Figure 1 Processing procedure of *injera* made from teff millet – Ethiopian traditional fermented flat bread. (Adapted from Obilana AB, and Manyasa E (2002) Millets. In: Belton PS and Taylor JRN (eds.) *Pseudocereals and Less Common Cereals*, pp. 177–217. Berlin: Springer.)

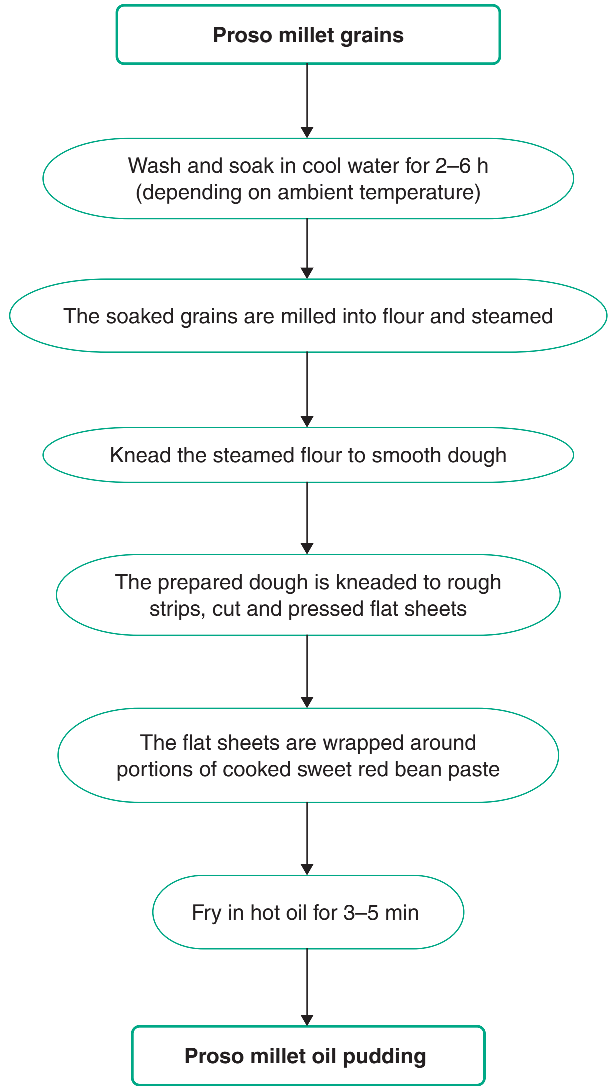

Figure 2 Preparation method of proso millet oil pudding – Chinese local traditional food. (Adapted from Lin RF, Li WD, and Corke H (1998) Spotlight on Shanxi province China: its minor crops and specialty foods. *Cereal Foods World* 43: 189–192.)

preparation is shown in Figure 2. The millet oil pudding is immediately eaten after frying. Color of its outer surface is normally pale. It has a delicate texture inside and has a sweet aroma. Proso/broomcorn millet sour meal is another traditional local food in Shanxi province for 400 years. Millet grains are poured into the prepared special sour soup (made from fermented soybean flour) with sweet-sour flavor, stirred, and soaked overnight. The soaked sour millet grains are used to cook final sour meals (sour porridge or sour millet rice). Sweet potato or yam is added into the soaked sour millet grains to cook the best sour porridge.

Indian chapati or roti (unfermented bread) is prepared from finger/pearl millet flour or composite flour mixed with others (e.g., sorghum). The processing procedure is traditional and simple, as shown in Figure 3, although there are some minor regional variations in the procedures throughout India. Indian “dosa” is fermented bread prepared from millets or mixed with other cereals and pulses. Dosa preparation is different from chapati preparation and takes more time, mainly due to the addition of a fermentation operation. For instance, millet grains and black gram are mixed in a ratio of 3 : 1 by volume and wet-ground. The mixed batter needs to be fermented overnight. Additionally, popping of finger millet is common in India on a cottage-industry level. Some popped meal is packed in polythene pouches for marketing.

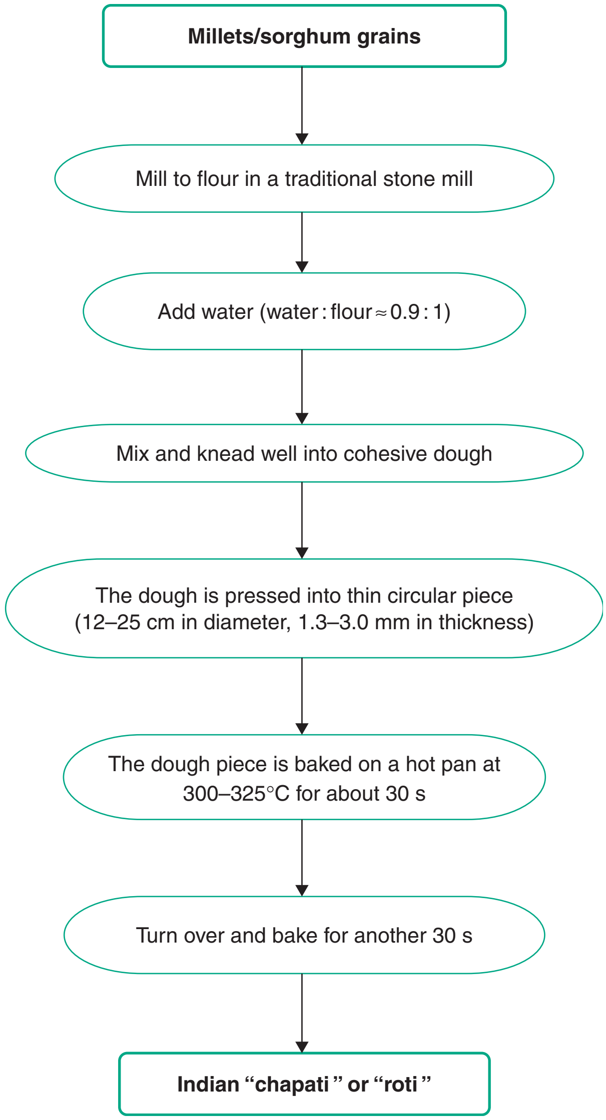

Figure 3 Traditional preparation of "chapati" or "roti" made from finger/pearl millets or mixed with sorghum – Indian unfermented bread. (Adapted from Murty DS and Kumar KA (1995) Traditional uses of sorghum and millets. In: Dendy DAV (ed.) *Sorghum and Millets: Chemistry and Technology*, pp. 185–221. St. Paul, MN: American Association of Cereal Chemists.)

Most millets, like wheat, contain a similar level of protein and a large quantity of starch, but the physiochemical properties of millet flour are different from wheat flour. Because millet flour does not have gluten, it is difficult to use 100% millet flour to produce wheat flour-like food products. However, millet flour can be mixed with wheat flour and other cereal and pulse flours into composite flours to process baking foods, noodles, cookies, weaning foods, extruding foods, instant powders, healthy foods, etc. These millet-based foods are, to a certain extent, acceptable and their processing techniques are available in some millet production countries, especially in India and China. Their production can be carried out using modern baking, extruding or expansion technology and other ordinary processing methods. For example, both commercial and experimental weaning foods have been successfully made from millet flour mixed with other cereals and pulses in India. The millet-based weaning foods have good quality with desired nutrient compositions within the range prescribed by the India Standard Institute for processed weaning foods. In northern China, some village/town-owned and small state-owned food factories have commercially or experimentally produced a wide range of millet-based composite flour dry noodles and other local/traditional food products containing various types of small grains.

More research work is needed on minor millets to enhance large-scale industrial utilization and commercialization of traditional millet foods and development of millet-based specialty food markets. This work will be useful for alleviating food shortage of the poor and also helpful for increasing the value of millets and accelerating agricultural improvement in developing countries.

MILLING AND BAKING, HISTORY

C E Walker and W D Eustace, Kansas State University, Manhattan, KS, USA

Introduction

The histories of milling and baking parallel each other, as have developments in their technologies. Mutually dependent upon each other, they originated together and remain inextricably linked, even though the two fields have specialized and separated to the point that many people no longer consider them together.

Flour Milling

Volumes have been written on the history of milling and how it parallels the development of civilization. So much has been written that we can only hit the high points without much detail. It has been said that if we compare mankind's time on earth to a 60 min period, milling started 55 min after his appearance. Agriculture started 4 min later and recorded history 30 s after agriculture. These observations lead one to believe that grain milling may be the oldest manufacturing process in the world.

Man probably used stones to break up nuts, berries, grains, and bones to produce food that was easier to chew. The basic process of pounding or rubbing between two stones went on for thousands of years. A saddle stone was found in an Egyptian tomb built around 3660–80 BC. Milling and baking scenes have been found on walls of Egyptian tombs dating from 2600 BC. The drawings show grinding with saddlestones and separating the meal with sieves made of papyrus or horsehair. Saddlestones produce a rubbing or attrition action, making a better separation of bran from endosperm as compared to pounding, which pulverizes the entire kernel. The use of sieves with saddlestones became a popular means to separate the meal from the bran particles. Many versions of the saddlestone have appeared but the back and forth

motion required hours of back-breaking labor to produce enough meal to feed a small family. Saddlestones are still used in many parts of the world.

Rotary Motion

Around 800 BC, rotary motion was applied to a device called a quern, which is made up of two horizontal circular or conical stones with one on top of the other. A device called a rynd supported the upper stone, allowing a slight gap between the two grinding surfaces. The upper stone was turned while the lower stone remained stationary. Going from reciprocating to rotary motion was a tremendous step forward. The advantage of rotary motion was the continuous application of force in one direction using wind, water, animals, or people as a source of power.

Water was used to turn millstones around 19 BC by the Roman architect Vitruvius. The millstones were 2–3 ft in diameter and ~6 in thick. The application of water power through a gear mechanism laid the foundation for heavy industry. Gears had been described by Aristotle in 400 BC. Ctsesbus in 200 BC used gears in various clock movements where the forces were very light. The mill by Vitruvius was the first recorded use of gears in a massive mechanism designed to do productive work. Figure 1 shows the evolution of stone mills.

The millstone became a machine capable of working for extended periods of time, instead of being a hand tool producing large quantities of flour. This meant that the strength of the people or that of animals was not a limiting factor anymore. It is interesting to note that, except for subtle differences in design, the millstone has remained unchanged for over 2000 years.

Windmills were utilized in eastern Iraq by CE 644. A mill of this type is most efficient when built in an area that has winds blowing without changing direction. Western Europe had windmills by CE 1145. The use of windmills increased in number until the invention of the steam engine by James Watt in 1769. Steam engines were applied to stone mills in 1786; that allowed the construction of mills in areas that did not have reliable water or wind sources.

Milling with stones was a “sudden death” or “low grinding” process in which the wheat kernel was reduced to meal in one pass through the millstones. Some bran might be removed by sifting but a large amount would be reduced to meal or flour size and included with the final product. This was more of a problem with hard wheat than soft wheat.

High Grinding – Gradual Reduction

Towards the close of the sixteenth century, the French miller Pigeaud developed a new system. Instead of passing the wheat once through the millstones, he ground it three or four times with sifting between each pass. On the first grinding, the upper millstone was raised slightly giving a larger gap. Sizings and middlings were produced with minimum flour. After sifting, the “overs” of the reel or sieve were ground again with a slightly smaller gap to remove the coarser endosperm particles. The endosperm collected was ground with a very close gap to produce as much flour as possible. This procedure gave higher quality flour than single pass “sudden death” milling.

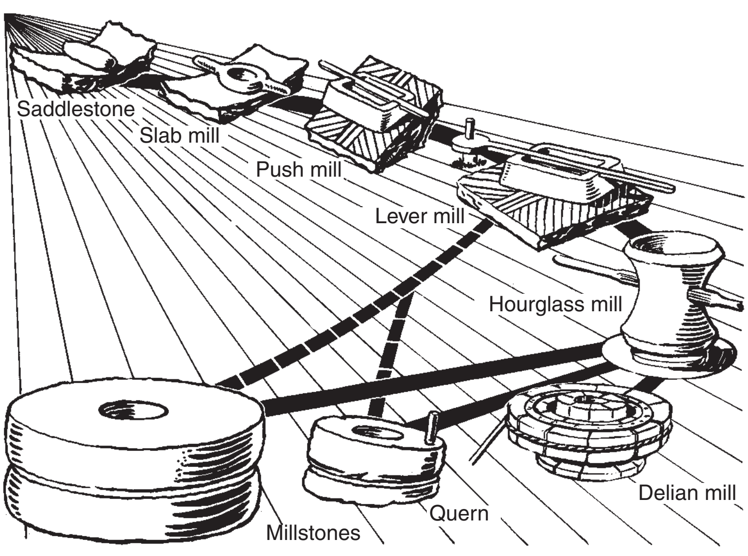

Figure 1 The evolution of the stone mill, from the hand operated saddlestone to powered millstones. (Reproduced with permission from Storck P and Teague WD (1952) *Flour for Man's Bread*, 76p. Minneapolis: University of Minnesota Press.)

Because of the better quality flour produced the method of "high grinding" spread rapidly in Europe and America. This was the start of the gradual reduction system.

The Hungarians improved the system by using a purifier developed by Ignaz Paur in 1807 to grade middlings produced on the first several passes through the millstones. This was especially desirable for hard wheat, which tended to produce coarser endosperm particles than soft wheat. With the Hungarian system, workers collected the product from each machine and transferred it by hand in buckets to the next operation. This required a lot of hand labor that was supervised by the miller who made the decision where each separation was sent. At that time the Hungarian system was the most complicated milling process but it produced the best flour.

The development of particle size classification ranged from handpicking, hand sieves, oscillating sieves, shaking sleeve bolters, cloth-covered reels with internal brushes, polygonal and cylindrical-sieving reels, and centrifugals, which are slowly revolving reels with rapidly revolving internal beaters. The Egyptians used hand sieves, but their capacity was limited. The brush sifter was a stationary inclined reel that had revolving brushes inside that forced the fine stock through the screen. John Milene patented this particular machine in England in 1765.

Reels varied in length from 12 to 28 ft (3.6–8.5 m) in length and 20–36 in (0.5–0.96 cm) in diameter rotating from 30 to 35 rpm. Capacity varied from 300 to 2800 lbs (136–1270 kg) per hour depending on mesh size and type of stock being sifted. Reel efficiency was low because only about one-third of the surface was used as the reel rotated. Rotating centrifugals had higher capacity than stationary centrifugals.

Plansifters made their appearance around 1880. Karl Haggenmaker of Switzerland built the first serious plansifter in 1888. The early plansifters were only three or four sieves high and were not free swinging. Free-swinging self-balancing sifters were developed in the US and Europe in the early part of the twentieth century. These sifters now come with 12, 17, 22, or 27 sieves per section.

A carpenter working in a French mill around 1775 invented what is regarded as the first purifier. This machine and others after it used air currents blown through falling stock to separate bran particles from heavier endosperm particles. These machines generated a lot of dust in the mill. In 1855 another Frenchman, Cabane, used air-aspirated sieves as a purifying device. The sieves separated sizings and middlings according to size and removed bran by air. The development of the purifier allowed the miller to produce white flour from hard wheat that would compete with soft wheat flour in terms of color.

George Christenson had Edmund La Croix install a purifier in the Washburn mill in Minneapolis, Minnesota in 1870. This machine was different from the previous purifiers because it used a reciprocating sieve with air drawn through the cloth by negative pressure rather than positive pressure. This particular arrangement was based on a patent held by a Frenchman, Perrigault. The only problem with the Perrigault purifiers was the lack of a way to keep the sieve meshes clean. A mill employee, G. J. Smith, developed a traveling brush to clear the meshes and obtained a patent on the change in 1877. Since then, improvements on the basic purifier include air adjustments, drives, number of decks, cloth cleaners, sieve construction, clothing, feeding arrangements, and internal lighting.

About the same time that the purifier was being developed, Oliver Evans, an inventor unfamiliar with milling, contracted to build a mill near Wilmington, Delaware, USA. He wanted to build a mill that was better than any other previously constructed. He concentrated on using waterpower to drive conveyors moving stock in the mill. This would greatly reduce the manual labor requirements in milling. His mill, using bucket elevators, screw conveyors, and gravity spouts to move stock during processing, was the beginning of automatic milling. This allowed the miller to concentrate more on the milling process. The Evans mill started running in 1785 and eventually became the model for mechanized large-scale mills in the nineteenth century (Figure 2).

Roller Mills

When the purifier came into general use, it started what was called "new process" milling because of the millers ability to produce flour superior to any previously produced. Combining the purifier and Evans automatic mill started a revolution in American milling that spread to Europe. About this time roller mills were starting to appear. The concept for the roller mill is credited to Giovanni Torriano in 1558 in Spain. It consisted of a hand-powered corrugated cone working inside a curved corrugated shell. Recorded history shows nothing else about roller mills until 1774 when a patent was granted in England for a roller mill to grind corn. However, nothing was mentioned historically until Helfenberger built his first roller mill in 1820. This attempt was not very successful.

Muller, a Swiss in Warsaw, Poland, made progress with improvements on the roller mill design in 1822. He constructed an all-roller flourmill in 1833 that failed almost immediately because of improper

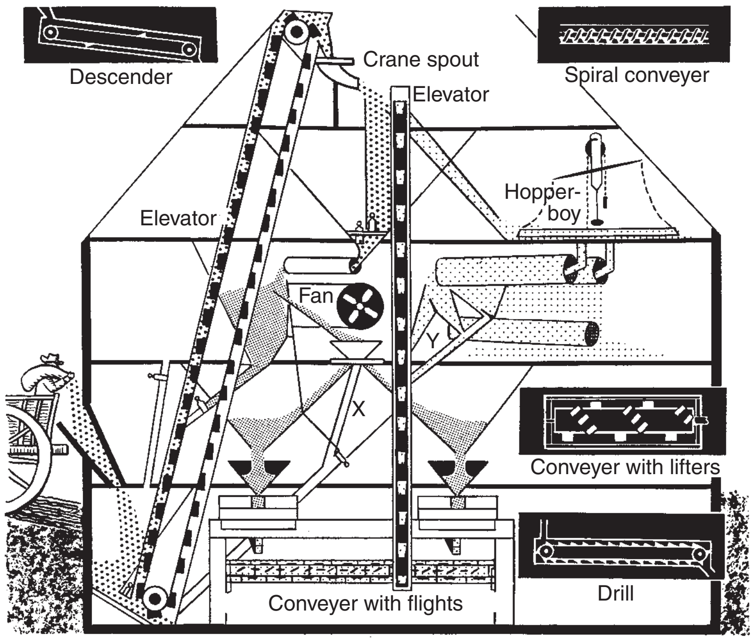

Figure 2 Oliver Evans 1785 "mechanized" flour mill, showing mechanical conveyors. (Reproduced with permission from Storck P and Teague WD (1952) *Flour for Man's Bread*, 71p. Minneapolis: University of Minnesota Press.)

placement of equipment in the flow. Another Swiss engineer Jakob Sulzberger was assigned to reconstruct the mill. His changes were so successful that numerous other flourmills were constructed to use roller mills. The mills used both roller mills and millstones in the flow. The break stages used rollers while the reductions used millstones. Apparently at that time, millstones were more efficient for grinding sizings and middlings than were rollers.

Roller mill development in relation to milling took place in Europe, particularly in Hungary, around 1877. The early roller mills were not very effective until high grinding or multi-pass grinding, which started in France, developed further. Later roller mills gave better control over grinding because of even distribution of stock to the nip of the rolls. Also, the gap between the rolls could be controlled more accurately to maintain even grinding. Early roller mills had steel rolls from 4.5 to 9 in (114–229 mm) in diameter. Porcelain rolls were tried but they wore out more quickly than steel.

Today's modern roller mills are set up to engage when stock is coming to the roll stand or disengage when the stock runs out. Feeder rolls automatically increase or decrease the stock to the rolls to maintain an even load to the length of the rolls. Newer roll stands can be programmed to automatically change roll gap when changing mill mixes. Double high roller mills are being used on selected break and reduction passages. This helps to eliminate sifting.

When roller mills were first introduced in mills using millstones, problems arose. First the capacity of the early roller mill was at least double that of a millstone. This required more handling and processing equipment. Reels could not handle the load, so the miller had to install more reels or go to plansifters both of which were more costly. Increasing capacity to cover the cost led to increased competition among the mills, driving many small operations out of business.

Milling was rapidly becoming a narrow-margin, high-volume, manufacturing process. That trend has continued unabated until today.

Grain Cleaning

Grain cleaning was slower in developing, as compared to milling. Early man probably removed some impurities by hand before and after grinding grain. Sifting of the meal after stone grinding probably removed more impurities. A specific reference to grain cleaning was made by Oliver Evans in the mill he designed and built in 1783. Evans mill design scoured the grain between two stones then sent it through a revolving cylinder screen that had a fan for aspiration.

Frederick Kick, in 1888, discussed several grain-cleaning methods, one of which was throwing the grain into the air by shovel or hand. When the grain was thrown the heaviest kernels flew the farthest, while chaff and light kernels traveled the least

distance. If a current of air blew across the airborne grain the separations were cleaner. This process took a lot of practice and was not suitable for large quantities of grain.

Kick classified grain-cleaning machines at that time into three categories:

1. dressing machines with sieves;
2. machine separating round seeds from wheat; and
3. machines for sorting grain.

Category 1 used sieves with air blowing through the grain as it passed through the sieve. Grain and impurities larger than wheat passed over the screen, while wheat and impurities the same size or smaller than wheat passed through the screen. Air blowing on the material through the sieve removed chaff and dust.

Category 2 used inclined surfaces to separate round seeds from wheat. Revolving cylinders with the first half perforated and the last half with indented areas are also included in this category. The perforations removed impurities smaller than wheat while the indents lifted round seeds that were the same diameter as wheat and dropped them into a trough in the cylinder above the grain flow.

Category 3 was an inclined reel made of perforated sheet metal or wire with the smallest openings at the head end and largest openings at the discharge end.

Wheat tempering (adding water to the mill grist to toughen the bran so it would not shatter) was also practiced but moisture control was difficult. Moisture determination of grain was time consuming and the control of moisture added was almost nonexistent.

Kick observed that corrugated rolls became dull because of the sand and small stones that were always in the wheat. This observation indicated that grain cleaning at that time had a lot of room for improvement.

Baking

The history of baking dates back to well before written history, far back into antiquity. No one knows exactly when and where baking (and hence the oven) was discovered, but the Egyptians had well-designed ovens operated by skilled career bakers. The origin of milling may have preceded baking, probably coinciding with early nomadic tribes grabbing grass seeds, predecessors of present-day oats, barley, rye, and wheat, to chew on as they wandered across the savannas. Eventually they discovered that rubbing some of the husks off (the origin of milling) and then soaking the seeds in water, made them easier to chew and more palatable. Perhaps someone accidentally splattered some thin gruel on a hot stone to make a crisp, tasty snack. Or perhaps someone left a pot of porridge to set and some wild yeast, probably mixed with lactic acid bacteria, fell into it. The owner may have drunk it that way, or perhaps let it dry up in the pot while it was sitting in the coals, forming a flavorful hard cake. The dried cake didn't spoil. It could be carried on the hunt, softened in water, and eaten without taking time to gather grains. It could even be stored in the cave to eat when prey was difficult to find. At any rate, harvesting cereal grains, milling, baking, and brewing appear to have a common ancestor and are closely related even today.

Ovens

Baking gradually evolved from bare coals and hot rocks into the more sophisticated practice we know today. Archaeologists have discovered the remains of ovens, grain bins, and grinding slabs dating from 7000 to 5600 BC in the Jordan valley of Jericho and of Hacilar in Turkey. Just as in nearly all other forms of technology with which we are familiar today, when civilization developed new baking equipment and techniques, it left some people behind who did not adopt it, keeping the ancient forms alive. Someplace in the world today, a woman is still baking her family's daily bread using a rock sitting in a bed of coals. Perhaps someone is still following the ancient nomadic practice by baking their bread on dried camel dung, providing the hearth and the fuel source all in one. By 3000 BC, the organized and agrarian Egyptians were using thick earthen jars sitting in coals to bake bread. And as before, the heated earthen jar evolved into the tandoor ovens still in common use in India and the Middle East. A piece of fermented dough is slapped onto the inside of the hot jar. When it falls off, it is baked. At ~1000 years BC, the same time that bakers learned to preserve their sour dough for the next day's production, they developed the ancestral bee-hive oven design (Figure 3). A stone or clay domed roof sat on top of a flat stone hearth. First, a fire was built inside until the oven was extremely hot throughout. Then the fire was scraped out, the inside swept free of ashes, and the fermented dough pieces placed on the hearth to bake.

Ovens changed slightly in form, but did not leave the basic "hearth inside a chamber" design until the 1800s, only two centuries ago. The Egyptians passed their technology to the Greeks who in turn passed it to the Romans. The Romans understood milling, sifting, fermentation, and baking, and distributed the knowledge throughout their empire, spreading it to Europe. The bakers were sometimes highly regarded and skilled people, and at other times they were slaves to the wealthy. Most bread was still baked at home or in communal ovens. Little change in baking technology occurred from the fall of the Roman Empire through the Middle Ages. Civilized society nearly

vanished from Europe until the eleventh century crusades brought the travelers into contact with other cultures, exposing travelers to their baking methods.

By the late eighteenth century, the beehive oven had evolved into the ancestral "deck" oven and for larger capacity, the deeper "peel" oven. Both designs live on today, baking pizzas and hearth breads. About this time, though, the heating methods begin to change. For thousands of years, the fire was placed directly in the oven to heat it, the fire was removed, and the bread baked as the oven gradually cooled (Figure 4). A huge advance occurred when the fire was located in a separate firebox, removing much of the soot, ashes, and dirt from the bakery. By 1900, large commercial bakeries were producing 25% of the bread in the USA, mostly in large peel ovens as much as 6 m (20 ft) long. A long-handled paddle (peel) was used to place the dough pieces onto the hearth, loading the oven from the back to the front. The same peel was then used to remove the baked bread, from front to back. The result, of course, was that the loaves received a different bake, depending upon where in the oven they were placed. By the late nineteenth century, bakeries began to mechanize and a wide variety of ovens evolved, finally breaking away from the hot masonry chamber into which loaves had been loaded and removed, one at a time, for many centuries past.

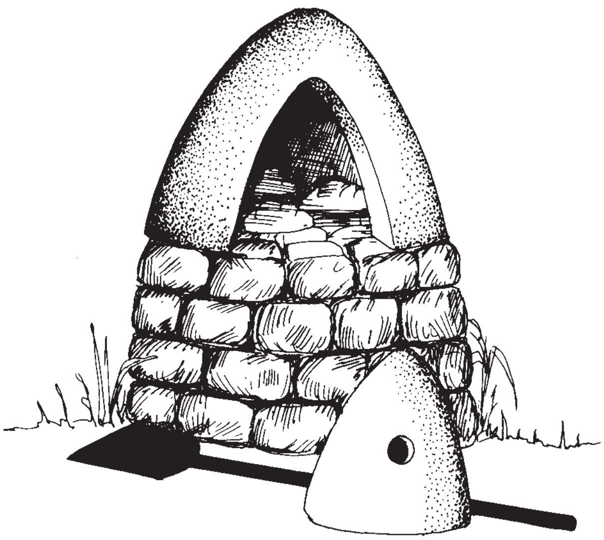

Figure 3 Beehive shaped ovens have been used to bake breads for thousands of years. (Reproduced with permission from Varilek PS and Walker CE (1983a) Baking and ovens: history of heat technology. Part I. *Baker's Digest* 57(5): 52–54, 56–57, 59.)

(Reproduced with permission from Varilek PS and Walker CE (1983a) Baking and ovens: history of heat technology. Part I. *Baker's Digest* 57(5): 52–54, 56–57, 59.)

Baking Classifications

Baking today may be classified by several methods: scale, food being baked, physical arrangement, and energy source.

Scale

Today's small "corner hot bread shop" or "in-store bakeoff" may use small batch ovens that only operate a few hours per day, perhaps baking only a hundred loaves. The "baker" only needs to put the loaves (sometimes frozen doughs or even par-baked loaves) into the oven and remove them when the buzzer sounds. Larger-scale bakers are probably using rack or reel ovens, still manually loading them a batch at a time. They may bake a few hundred to a few thousand loaves per day. More judgment and skill is required on the part of the baker because the entire operation is probably a "scratch" bakery, preparing doughs and batters from individual ingredients, not from mixes or frozen items. Finally, modern large-scale high-speed plant bakeries produce 100 loaves per minute on each of several lines.

Food Being Baked

Except in very small bakeries, breads are baked in different ovens from sweet doughs, such as yeast-leavened pastries. Cookies and crackers will be baked on a different design yet, and cakes and pies require still different designs. While smaller bakers may use a "one for all" oven, by far the best results

will be obtained using an oven designed for the specific food type.

Physical Arrangement

Different physical arrangements for ovens began with the descendents of the primitive beehive ovens, such as hearth or deck ovens, rotary hearth, rotary rack, reel, traveling tray ovens with single or multiple laps, and finally today's long, continuous tunnel ovens used for crackers and cookies.

Heat Sources

Except for small or primitive bakers and a few "boutique" bakers, wood is seldom used today. Refined petroleum, natural gas, or electricity are the most commonly used heat sources. Individuals living in very hot and sunny countries with a shortage of fossil fuels may use solar energy in a few isolated locations. Coal, once common, is now seldom used because it is so dirty. Modern ovens may combine several forms of heat and heat transfer, including high velocity air jets as in the present day pizzeria ovens, or adding microwaves to existing units to make them bake faster.

Other Changes in Baking

As bakers progressed with technology, their way of life changed. First, one person, usually the wife/mother, gathered the grains, threshed and milled them by hand, mixed the dough, and baked it on her cooking fire. As harvesters, millers, and bakers began to specialize and fall into the male domain, their operations got larger and they began to develop machinery. Automation entered the bakery after it had already set milling onto the path that led it to today's large and efficient plants. Their paths were similarly taken.

Early "large-scale" bakers often crawled into their wooden troughs to knead their dough with their feet. Then, larger and more efficient mechanical mixers were developed, especially with the advent of electric motors. As each stage was mechanized, the increasing capacity put pressure onto each stage that followed, in a stepwise fashion.

Mixed fermented doughs were divided, rounded, and molded automatically. Pans were filled automatically. Ovens were made continuous instead of batch, so conveyors were developed to load and unload them. The loaves were de-panned by machinery and the loaves sent through large cooling conveyors.

Individual loaf-protective wraps began to appear and antimold preservatives were added as bakeries became larger and larger and their delivery routes began to stretch across state lines. The advent of pre-sliced bread put additional demands upon technology and formulation. Special fats were added to retard staling. In the 1940s, wartime labor shortages encouraged the development of even more highly automated continuous mix – continuous baking processes that produced bread with very fine cake-like crumb grain and a very soft texture. The shelf life of white pan bread extended from hours to days to a week. Recent advances have led to 2 weeks or longer shelf lives.

Future Challenges

The grain producing, milling, and baking industries today face steadily increasing challenges. The expectations for more grain at a cheaper price to feed an expanding population conflicts with the farmer's dream for more profits. The millers and the bakers face the same conflicting expectations. The results have been steadily more sophisticated and automated systems, from the field to the table. This has resulted in a large, highly efficient, standardized process producing a similar product everywhere, the same product from all plants for all customers.

As any society becomes more efficient and more affluent however, it begins to demand and to be able and willing to pay for more specialized consumer goods, including breads. The proliferated demands in the 1990s for a wider variety of bread types, once available only from the small artisan bakers, has caused other competing demands on the large bakers. Perhaps they can now develop easily modified automated means to produce a wider variety of breads, cakes, cookies, and pies by computer control over the entire baking process, from initial ingredient selection and mixing through forming, baking, finishing, final packaging, and distribution.

N

NITROGEN IN GRAIN PRODUCTION SYSTEMS

X M Zhou, McGill University, Ste-Anne-de-Bellevue, QC, Canada
B L Ma, Agriculture and Agri-Food Canada, Ottawa, ON, Canada
D L Smith, McGill University, Ste-Anne-de-Bellevue, QC, Canada

Introduction

Nitrogen (N) is the largest component of the Earth's atmosphere, comprising ~78% (by volume) of the air we breathe. It is usually present in the atmosphere as a dinitrogen gas (N_2), which is colorless, odorless, tasteless, and relatively inert at room temperature.

Nitrogen was first identified by the chemist and physician Daniel Rutherford in 1772. It is now known to be present in a vast range of materials encountered in our day-to-day existence; foods, fertilizers, poisons, and explosives are a few general examples. Some specific examples are: nitrogen gas is used as a blanketing medium during the production of electronic components, as an agent for annealing stainless steel, in beverage processing, as a refrigerant for food protection and preservation, and as a major fertilizer in crop production. Atmospheric nitrogen is also responsible for the orange-red, blue-green, blue-violet, and deep violet colors of the aurora. More importantly, N is a component of a wide range of biological compounds, being fourth in abundance after carbon (C), hydrogen (H), and oxygen (O).

Nitrogen exists in organic and inorganic forms in the atmosphere, biosphere, hydrosphere, and geosphere. It can be present in gas, liquid (dissolved in water), or solid phases. The most common inorganic forms include dinitrogen (N_2) gas, nitric acid (HNO_3), nitrate (NO_3^-), nitrite (NO_2^-), ammonium (NH_4^+), gaseous nitrous oxide (N_2O), gaseous nitric oxide (NO), gaseous nitrogen dioxide (NO_2), and gaseous ammonia (NH_3). The most common N-containing biomolecules belong to one of the following three chemical families: proteins (including enzymes) and related compounds (including peptides and amino acids), nucleotides (largely RNA and DNA), and porphyins (e.g., cytochromes and chlorophyll).

Although N constitutes only 1–7% (w/w) of plant dry matter, it is the element most frequently limiting the plant growth. Sufficient nitrogen is fundamental for crop growth, development, and yield. Improvement in N use-efficiency is thus the key to produce safe and high-quality food and feed in an environmentally responsible way.

The Nitrogen Cycle

Nitrogen is a dynamic element and is recycled continually by plants and animals. It can be transformed from one oxidation state to another through processes that comprise the N cycle (Figure 1). The term "cycle" is really a misnomer as the pathways of N in the biosphere are actually a simple web. Nitrogen moves among oxidation states, with ammonia (NH_3) being the most reduced and nitrate (NO_3^-) the most oxidized. The tremendous chemical stability of dinitrogen (N_2) gas makes the conversion of this compound into ammonia (NH_3) or oxides of N (NO_3^-) energetically expensive and the rate-limiting step in this part of the "cycle." This causes N_2 to accumulate in the atmosphere. Thus, cycling of nitrogen by various biological entities determines a major part of the composition of the Earth's atmosphere.

It is a paradox that while 78% of the Earth's atmosphere is N_2 gas, and plant stems, leaves, flowers, and fruits are immersed in this gas, biologically available N is generally the most limiting nutrient element for crop production. A solution to this problem evolved in the exquisitely adaptable prokaryotes. A limited number of microorganisms are able to react N_2 with electrons to form NH_3, which they then incorporate into various biomolecules. When these microorganisms die, N is mineralized to simple forms (NH_3, NO_3^-) through decomposition by other microorganisms. In these forms, N is available to higher plants. Nitrogen is taken up by crop plants, which become food for animals, including human beings, and energy sources for bacteria or fungi; N is then

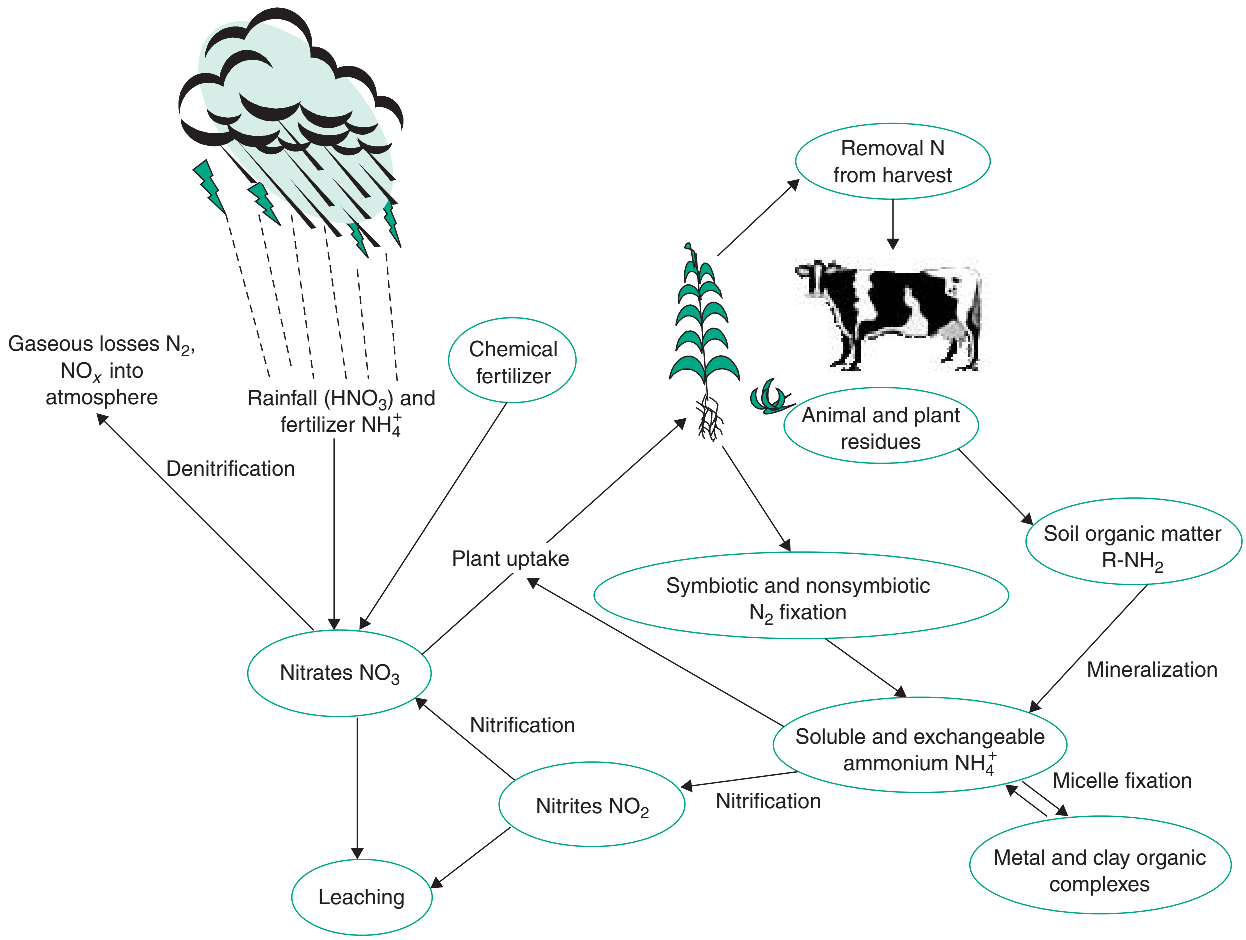

Figure 1 A diagram of the N "cycle" in a typical grain crop containing agri-ecosystem.

cycled back to the soil when dead cells and tissues of organisms (plant debris for example) or N-containing waste products (such as animal urine and feces) are broken down by soil microbes.

In natural ecosystems, N changes from one form to the other, but most of it remains within the nearly closed system in a dynamic balance. In agricultural systems, humans often add chemical N, fixed through industrial processes, a significant portion of which is eventually removed from the field in harvested material. Food, fiber, and livestock are now often produced primarily in one location and transported to other regions of the world for consumption, making crop production fields into nutrient flow-through systems. Nitrogen input into agriculture production systems is largely from chemical fertilizers, or N-fixing crops (including those grown as green manures). There are other minor sources, such as biosolid waste products, which are sometimes added to croplands. A small amount of N comes with precipitation, sometimes associated with lightning discharges, which reacts the N_2 and O_2 in the atmosphere. There is some N-cycling within agricultural systems, with livestock manures constituting the major component of this process.

Nitrogen outputs from crop production systems include removal of harvested grains and forage biomass from production systems and losses of various N forms through runoff (surface water), leaching (to ground water), denitrification (production of gaseous N_2O), and volatilization (generally NH_3). Because of leaching and gaseous losses, and aspects of plant N physiology, only ~50% of the N applied to crop production systems is taken up by the plants, with the remainder being unusable or lost. Globally, various forms of N are in a dynamic balance.

Soil microbes play a wide range of roles in the N cycle. Because of this, these processes are dependent on temperature, moisture, and the quality and quantity of soil organic matter available to them. It is microbes that break down most of the organic material, leading to "mineralization" of organic N. Microbial populations in the soil can take up large amounts of N released from decomposing plant tissues, as long

as there is sufficient reduced carbon available, leading to "immobilization" of N. The conversion of ammonium (NH_4^+) to nitrite (NO_2^-) and to nitrate (NO_3^-) is referred to as nitrification. All forms of N in the soil (except N_2 gas) can be converted to NO_3^- by soil microorganisms, under aerobic conditions when soil temperatures are above freezing.

The amount of nitrification is controlled by the supply of NH_4^+ which is, in turn, controlled by decomposition rates, plant and microbial growth, and soil pH, or by N-fertilizer addition rates. Nitrate can be converted back into N_2, or into nitrous oxide (N_2O), through denitrification. This process often takes place under anaerobic (generally water saturated) soil conditions. In this process, soil NO_3^- can be reduced to N_2 gas through a series of intermediate steps [$NO_3^- \rightarrow NO_2^- \rightarrow NO$ (gaseous nitric oxide) $\rightarrow$ N_2O (gaseous nitrous oxide)] and finally to N_2 (gas). The intermediate and final products of denitrification, are released into the atmosphere. Denitrification may lead to the loss of 4–5% of soil NO_3^- each day when soil remains water saturated. Microbes play a key role in most aspects of the N cycle, generally extracting energy by converting forms of N out of equilibrium with the oxidation state of their environment into forms that are in equilibrium, and extracting a reasonable portion of the energy liberated through this process. This causes N to move among forms that are biologically available or unavailable, mobile or immobile, oxidized or reduced, gaseous or solid.

Nitrogen Sources

Nitrogen exists in inorganic or organic forms in our environment. Inorganic forms include NO_3^-, NO_2^-, NH_3, and N_2 whereas organic N is found in a wide range of biomolecules. Protein is one of major classes of biomolecules and generally the largest repository of organic N in the biosphere. RuBisCo, the plant protein responsible for the uptake of CO_2 by C_3 plants, is the most abundant protein on the planet. The other two most abundant classes of biocompounds, carbohydrates, and lipids, generally have little N associated with them. Over 90–99% of N in the surface (or tillage layer; 0–25 cm) layer of most soils is in organic forms. Although there is an abundant potential supply of N in the Earth's atmosphere (N_2 gas), the unique geometry of the triple bond between the two N atoms results in a very stable compound that is very energetically expensive to break. Thus, this form of N cannot be used directly by most organisms. Whenever dinitrogen is converted into other forms, a large input of energy is involved. The major sources of this energy are: (1) lightning in the case of atmospheric fixation, which accounts for 5–8% of total N fixed and potentially available to the biosphere. This process results in the combination of oxygen from the atmosphere with dinitrogen, causing the formation of N oxides. These compounds dissolve in rain water and are carried to Earth; (2) reduced carbon and adenosine triphosphate (ATP) in the case of biological N fixation, conducted by certain prokaryotes alone or in symbiotic relationships with plants and sometimes animals; and (3) fossil fuels for industrial fixation.

Industrial fixation relies on the Haber–Bosh process, developed during the First World War for the production of explosives. This process uses a catalyst, high pressure, and high temperature (600°C), to combine N from the atmosphere with hydrogen (usually derived from natural gas or petroleum) to produce ammonia (NH_3). Ammonia can be used directly as fertilizer, reacted with CO_2 to form urea ($(NH_2)_2CO$), and/or oxidized to form nitrate (NO_3^-) which can be salted with other compounds (such as ammonium, NH_4^+) to form other types of N fertilizers (e.g., ammonium nitrate). The large requirement for energy makes N fertilizer easily the largest component of fossil fuel consumption in crop production, being close to 50% of the total for crops such as maize.

The bulk of the soil N in noncropland systems comes from fixation by symbiotic bacteria (largely genera associated with legumes and collectively referred to as rhizobia and species of *Frankia*, usually symbiotic with woody plants), fixation by free-living bacteria and mineralization of organic matter (N released as decomposition of plant and animal residues). The potentially available N (90–99%) in the soil is in organic forms, the rest being in inorganic (or mineral) forms. The organic forms are not immediately available for plant use and have to be decomposed by soil microorganisms through mineralization. In addition, a very small amount of organic N may exist in relatively small soluble compounds, such as urea or amino-sugars, which may be slightly available to plants.

Symbiotic (largely legume) N-fixation and mineral fertilizer N are the major sources of N for grain production systems, with animal and green manures, crop residues, composts, sludges, soil micro- and macro-biota being the other possible sources. Again, organic N must be mineralized before it is available to plants. Sodium nitrate ($NaNO_3$) and potassium nitrate (KNO_3) are formed by the decomposition of organic matter. In certain dry areas of the world, these saltpeters are found in quantity and are used as fertilizers. Other inorganic N compounds are ammonia (NH_3), nitric acid (HNO_3), the N oxides (NO, NO_2, NO_3, N_2O), cyanides (CN^-), etc. However, inorganic N in soil generally comprises only a small portion of soil N. Hence, despite N being

one of the most abundant elements on the biosphere, N deficiency is probably the most common nutritional problem affecting crop plant production worldwide.

Nitrogen Availability to Crop Plants

The availability of N sources is a fundamental requirement for metabolism as it allows N assimilation into amino acids (for which photosynthetically produced carbon compounds are also required) and their availability for protein synthesis. An adequate supply of N allows leaf growth and photosynthesis.

Inorganic (or mineral) forms of N, such as NH_4^+ and NO_3^-, comprise the majority of plant-available N. Other forms of N must be converted to one of these compounds by either natural or artificial means before they can be utilized by plants. When N is first released from organic matter, it is in the form of gaseous NH_3, which is volatile and can be lost to the atmosphere. When NH_3 dissolves in water, it acquires a proton and becomes ammonium (NH_4^+), which carries a positive charge and is attracted by the soil clay colloids and soil organic matter, which carry negative charges. Once attached to the soil matrix, $NH_4{}^+$ becomes part of the cation-exchange process whereby plants exchange a hydrogen ion (H^+) for one of the positively charged molecules in the soil. Only a small portion of the soil NH_4^+ exists in the soil solution; this NH_4^+ is available to crop plants. On the other hand, NO_3^- carries a negative charge, and so is not bound by clay particles. Thus, NO_3^- molecules are free to move with the soil water and are more readily available to crop plants than NH_4^+. However, in coarse textured or water-saturated soils, NO_3^- is much more prone to leaching into groundwater than NH_4^+; once in ground water NO_3^- becomes a potentially serious pollutant.

Nitrogen Fixation

A symbiotic relationship between leguminous plants and N-fixing bacteria allows for plant-based biological N fixation. The major conversion of N_2 into NH_3 (a biologically available form) is the biological N-fixation process, carried out by single-celled prokaryotes. This process requires a great deal of energy, supplied as ATP, which is derived from the breakdown of organic matter, or through photosynthesis (e.g., cyanobacteria). It is estimated that biological N fixation accounts for the annual production of as much as 250×10^9 kg of ammonia, which is twice the amount produced by the Haber–Bosch process.

Biological N fixation can be described as the following equation:

$$N_2 + 8H^+ + 8e^- + 16ATP = 2NH_3 + H_2 + 16ADP + 16Pi$$

This reaction is conducted by prokaryotes only (eubacteria and archea) through the enzyme dinitrogenase, and the closely associated dinitrogenase reductase. Dinitrogenase contains both iron and molybdenum in a cofactor referred to as FeMoco. The fixation of N is carried out while N_2 is bound to dinitrogenase. Dinitrogenase reductase (the Fe protein) is reduced by electrons donated by a protein generally containing ferredoxin. Reduced dinitrogenase reductase (Fe protein) binds ATP and reduces dinitrogenase (molybdenum-iron protein), which provides electrons to N_2 resulting in its reduction to $2NH_3$.

Due to its economic importance and agronomic value, the legume-rhizobia symbiosis is the most investigated process of biological N fixation. Many grain legumes are important crops due to this symbiotic relationship; these include soybean, bean, mung bean, faba bean, peanut, and pea as well as forage legumes such as alfalfa, clover, sainfoin, fenugreek, and vetch. During the establishment of this symbiotic process, rhizobia infect the roots of legume plants and cause the formation of nodules. It is in these nodules that the bacteria fix N and supply it to the plant. The plant provides reduced carbon (sugars) to the nodules, where it is converted to organic acids and supplied to the bacteria as an energy source. In most cases, the symbiosis can supply all N required for normal growth and development of the plant. The amount of N fixed by legume plants is estimated to range from 11 to 250 kg N ha^{-1} $year^{-1}$. When fertilizer N is supplied, N fixation is inhibited through several long and short-term mechanisms, so that adding N fertilizer to N-fixing legumes does not increase the amount of N available to the plants. For grain legumes, however, a small amount of starter N fertilizer greatly helps crop growth prior to the time when nodules become functional and begin to supply N. The simplest approach for evaluating whether nodules in field-grown legumes are able to fix N is to observe their interior color: effective nodules contain leghemoglobin and are bright red, while nodules not yet functional are generally white and those that are no longer functioning are generally greenish. Leghemoglobin carries oxygen into N-fixing (rhizobia containing) nodule cells, ensuring the availability of large quantities of oxygen, but in a very controlled fashion, to the nodule-enclosed rhizobia.

On the other hand, all field crops in the grass family, such as the grain crops maize, sorghum, rice, and

Table 1 Annual N inputs and outputs of typical agricultural land

	N (kg ha^{-1})
Inputs	
Plant residues	10–100
Biological N fixation	10–250
Natural fertilization through precipitation	0–50
Chemical fertilizer	0–400
Outputs	
Volatilization of NH_3	0–60
Dinitrification	10–70
Leaching	10–70
Crop harvest	10–150

wheat, as well as forage grasses, and also nonleguminous broadleaf field crops (e.g., sunflowers, potatoes, sugar beets, cotton, etc.) are unable to form N-fixing root nodules. Therefore, these plants must obtain their required N from the soil and other exogenous sources.

At present, almost 90 genera of diazotrophic bacteria, which can reduce atmospheric dinitrogen to ammonia with varying efficiencies, are known. Biological N fixation can be carried out by a wide range of prokaryotes, alone or in symbiosis, including cyanobacteria free living and in symbiosis in lichens, cycades, the fern *Azolla* or the angiosperm *Gunnera*; and free-living soil bacteria. These types of N fixation contribute significant quantities of NH_3 to natural ecosystems, but not to most cropping systems, with the exception of paddy rice. Their contributions are generally less than 5 kg N ha^{-1} year^{-1}. Table 1 indicates the general annual input and output of N in agricultural ecosystems.

Symbiotic Signals

Nitrogen fixing root nodules are the result of symbiotic interactions between leguminous plants and rhizobia. This begins with a recently elucidated signal exchange between the two symbiotic partners. Initially, the roots of leguminous plants secrete flavonoid compounds into the soil. These compounds activate a set of genes in the appropriate rhizobia. A structurally diverse mixture of lipo-chitooligosaccharides (LCOs) is produced by rhizobia after induction with flavonoids. LCOs consist of a chitooligosaccharide backbone of β-1,4-linked N-acetyl-D-gluconsamine (GlcNac) and a fatty acyl group attached to the nonreducing saccharide. Diversity of the fatty acyl substituents (length and degree of unsaturation) contributes to the diversity of LCOs. In addition, various groups can be added to the chitin backbone. The *nodE* gene determines the nature of the fatty acyl moiety, a major determinant of host range. LCOs are considered to be key factors in the specific recognition processes that underlie the formation of leguminous root nodules and their bacterial infection; in these associations only appropriate legume and rhizobium matches can come together and create a specific symbiosis.

Uptake

Nitrate (NO_3^-) and ammonium (NH_4^+) are the two major mineral forms of N taken up and assimilated by plants. These compounds enter the plant roots by diffusion through the space between root cells until they cross the plasma lemma and enter the plant cell interior. Once inside the symplast (for a review of the "symplast," see www.worldreference.com) these compounds can be stored in vacuoles, assimilated into amino acids or proteins or moved into the stele (xylem) for transport elsewhere in the plant. Movement among the cells that make up the symplast is through the plasmodesmata that connect plant cells. All mineral N must enter the symplast before entering the stele. This can happen at any point in the root cortex, but must happen by the time mineral N molecules reach the casparian strip. During the course of the vegetative growth, both NO_3^- and NH_4^+ enter the plant root and are transported via the xylem to the leaf (Figure 2). Once it reaches the leaf, nitrate reduction takes place, leading to the production of amino acids. Most of the newly formed organic acids are then translocated to the root where carboxyl groups are exchanged for an ammonium and the newly assimilated N is incorporated largely into leaf N compounds (protein). When a large quantity of N is required by developing fruits and filling seeds (reproductive growth stage), leaf proteolysis occurs and a great deal of the amino N in the leaf is ultimately exported to the filling fruits where it is accumulated as seed storage proteins (Figure 2). As a result, the phloem is enriched with amino compounds, which repress nitrate uptake and diminish the rate of nitrate reduction. Improved crop yield due to increased fertilizer N application suggested that the availability of N (usually nitrate in agricultural soils) is often the limiting factor in plant growth. The absorption of NO_3^- by roots is not only determined by the N demand of the plant, but also by its availability in the soil environment. Nitrate absorbed via roots is either reduced *in situ* into ammonium, imported into vacuoles (by high- and low-affinity transport systems) for storage, or transported via the xylem to the shoot where it can either be metabolized or stored as a reserve. A low-affinity root NO_3^- uptake system may play a greater role in nitrate uptake. In some cases, a high-affinity system has been shown to be

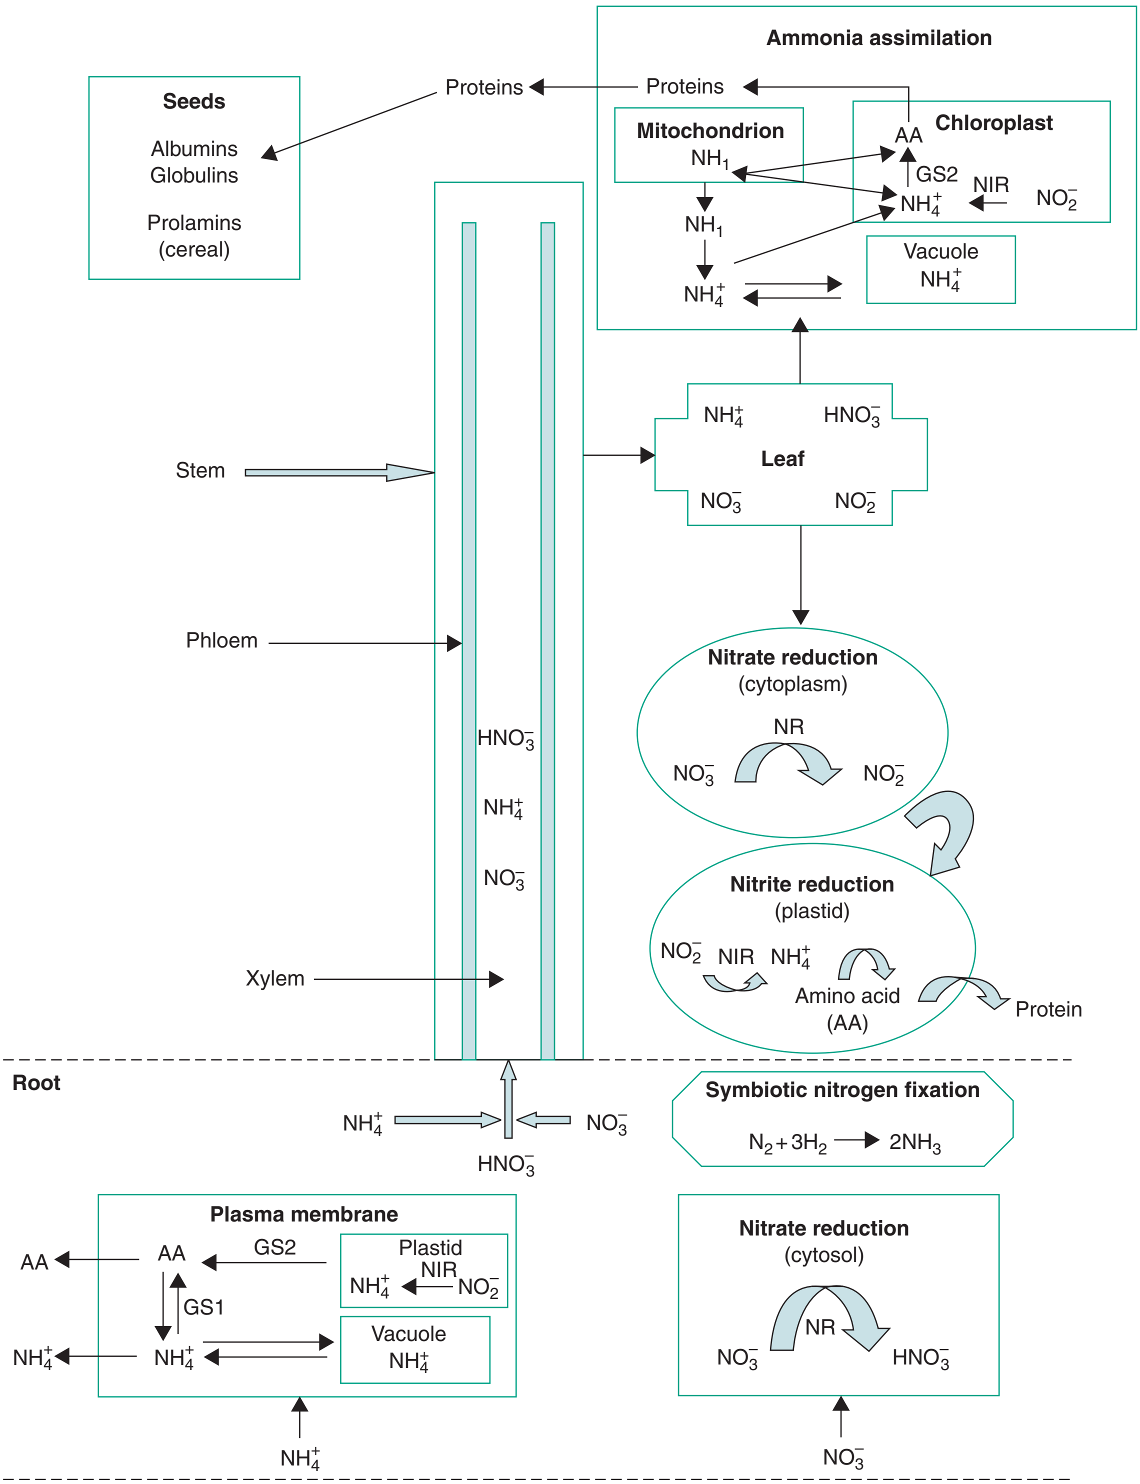

Figure 2 A diagrammatic summary of N metabolism in a grain crop.

the major mode of nitrate uptake through uptake competition studies and membrane voltage change studies. The low affinity transport system (LATS) (possibly a carrier system or an anion channel), and the inducible, high affinity transport system (HATS) are regulated by cellular energy supply, intracellular nitrate levels, and a proton electrochemical gradient. The latter is regarded as an H^{+}/anion cotransport carrier system that produces transient plasma membrane depolarization upon addition of nitrate.

The depolarization is counteracted by the plasma membrane H^+-ATPase. The plasma membrane proton ATPase is induced by nitrate. In addition to the nitrate uptake system, plants have an inducible nitrate efflux system, requiring both RNA and protein synthesis. The efflux system, however, has a much slower rate than the uptake system.

In the agricultural soils of tropical and temperate regions (except paddy rice fields), nitrate accounts for 70–90% of soil mineral N. Nitrate in the soil solution is 10 times more mobile than NH_4^+. Two reserves of soil NH_4^+ exist: a small portion of NH_4^+ is in the soil solution, and a large portion of NH_4^+ is adsorbed on soil colloids. Only water soluble NH_4^+ is available for plant uptake. Depending on the plant species, the bulk of the nitrate entering the plant is reduced to ammonia and assimilated into organic compounds in the roots or in the leaves. Plants can take up either NO_3^-, NH_4^+, or mixtures of the two. In most cases, crop plants perform better when the mixture of NO_3^- and NH_4^+ fertilizer is provided than either one alone. Uptake of NO_3^- by roots is governed by the concentration of NO_3^- in the soil solution, the volume of soil exploited by roots and root density within that volume, and plant demand for N, the latter being largely related to plant growth, development, and production. The root uptake efficiency of N is affected by metabolic demand, N concentration around the roots, and conditions such as temperature.

Ammonium is mainly assimilated in roots. It or alanine, formed by organic acid ammonization, is the main form of N exported from symbiotic N_2-fixing microorganisms to their host plants. In soil, NH_4^+ comes mainly from the mineralization of organic matter. When NO_3^- levels in the soil are low or completely exhausted, plants can rely on NH_4^+ released from cation-exchange sites or through mineralization of organic matter. During NH_4^+ assimilation in the root, excess H^+ is generated ($3NH_4^+ = 3R\text{-}NH_2 + 4H^+$) and released directly to external solution. While NO_3^- assimilation occurs excess OH^- is produced ($3NO_3^- = 3R\text{-}NH_2 + 2OH^-$). This excess OH^- may be neutralized by carboxylation or by $HCO_3{}^-$ released from the roots. Thus an H^+ neutral synthesis of plant materials can occur with a ratio of assimilation of $1NH_4^+$ per $2NO_3^-$. This is why many plant species grow optimally with a mixture of mineral N compounds (NO_3^- and NH_4^+). With a mixed N solution (NO_3^- and NH_4^+), NH_4^+ is often the form of N preferentially taken up by the plant. Many forest species take up primarily NH_4^+, since forest soils are relatively acidic, inhibiting the development of populations of bacteria that cause nitrification. The average NH_4^+ concentration in well-aerated soil is 10–100 times lower than NO_3^-, rarely exceeding 0.1–2 ppm. However, absorption of NH_4^+ by plant roots can occur at very high rates, due to the presence of transport systems in the root plasma membrane with high substrate affinities. Like NO_3^-, NH_4^+ uptake by roots is diurnally regulated, with maximum uptake during the light period. Uptake is stimulated by sugar supply, implying that the greater uptake during the day is related to the availability of photosynthate.

Assimilation of Nitrogen

Both nitrate and ammonium are taken up and assimilated by plants. In general, NO_3^- is the predominant form of inorganic N taken up by grain crop plant roots (except paddy rice). Under most circumstances, absorbed nitrate is reduced to ammonium in roots and/or leaves, and is then utilized in the synthesis of amino acids and proteins. Whatever the source of ammonium in plants, this ion is first converted into amino acids, the building blocks of protein.

Nitrate is assimilated into organic compounds by GS/GOGAT (GS – glutamine synthetase/glutamate synthase; GOGAT – glutamate oxidase, glutamine amino tranferase). The GS/GOGAT pathway is considered the major pathway for incorporating reduced N into organic molecules. This pathway recycles glutamate; amino groups are eventually transferred to other amino acids and utilized for protein synthesis and also for synthesis of other key biomolecules such as RNA, DNA, and porphyrins.

GS and GOGAT are located in the cytosol (for a review of the "cytosol," see www.worldreference.com) and the chloroplast (for a review of "chloroplast," see www.worldreference.com). Their activity in particular plant tissues is closely linked to specific primary N assimilation, NH_3 recycling during photorespiration, or general N remobilization. There are two pathways for incorporation of N into amino acids: (1) Direct incorporation where glutamate dehydrogenase is involved: α-ketoglutarate + NH_3 + NADH $\rightarrow$ glutamate + NAD^+; (2) GS-GOGAT cycle: GS catalyses the ATP-dependent conversion of glutamine utilizing ammonia as substrate and is represented by two protein groups, plastid (GS1) and cytosolic (GS2) isoenzymes; GS1 is located exclusively in chlorophyllous tissues while GS2 is located predominantly in roots, nodules, and floral organs. GOGAT catalyzes the conversion of glutamine and α-ketoglutarate to glutamate: glutamine + α-ketoglutarate + NADP + H + H^+ $\rightarrow$ 2 glutamate + $NADP^+$. The assimilation of NH_3 may be by either glutamate dehydrogenase or GS/GOGAT; the first of these requires quite high concentrations and the bulk of uptake is thought to be through GS/GOGAT.

Following the incorporation of NH_3 into glutamine, N can be transferred directly to the same position in asparagine by asparagine synthetase. Amino transferase can transfer the amino group to aspartate, which is converted to asparagine. It has been suggested that the reaction catalyzed by Fd-GOGAT is the key regulatory element controlling N partitioning and redistribution during plant growth and development. To date, research has focused on modifying ammonia assimilation in transgenic plants and this has demonstrated that the amplification or shifting of ammonium assimilation in a particular organ or tissue has strong effects on plant growth and development. Thus, there appears to be great potential for improving N-use efficiency in crop plants.

Reduction of Nitrate and Nitrite

Once NO_3^- enters the root symplast, it may follow five pathways:

1. efflux back to the apoplast [for a review of "apoplast" see www.worldreference.com];
2. reduction of NO_3^- to NO_2^-, then NH_4^+ by nitrate reductase (NR) using the reduced form of nicotinamide adenine dinucleotide (NADH) and by nitrite reductase (NIR) using ferredoxin (Fd) in root cells, leading to the production of amino acids;
3. accumulation into vacuoles of root cells, involving transport across the tonoplast [for a review of "tonoplast" see www.worldreference.com];
4. secretion into xylem vessels for long distance transport to the shoots; and
5. reduction of NO_3^- in the leaves, often using excess reductant in upper, CO_2 limited, leaves.

High concentrations of nitrate can be found in vacuoles, indicating that nitrate not only acts as a nutrient but also participates in osmotic maintenance. The first step in the nitrate assimilation pathway is the reduction of nitrate to nitrite, catalyzed by assimilatory NR. When reduction occurs in leaves, the nitrite formed by NR activity is then translocated to the chloroplast, where it is further reduced to NH_4^+ by NIR. During the nitrate reduction process, NR activity appears to be the rate-limiting step in the conversion of NO_3^- to NH_3/NH_4^+, because it is (1) the first enzyme in the pathway NO_3^- of assimilation, (2) substrate inducible, (3) relatively unstable, and (4) it's activity – relative to other enzymes in the NO_3^- assimilation pathway – is low and its K_m (related to binding affinity) for NO_3^- is high. Further, there is evidence that when nitrate is the dominant N source, nitrate reductase activity (NRA) is the limiting factor to the growth of many plants. NR has therefore been intensively studied in order to understand it's catalytic efficiency and regulation. Nitrite is reduced to NH_4^+ by NIR using ferredoxin (Fd). Nitrite reductase is located in plastids and possesses Fe–S and heme cofactors. Subsequently, the NH_4^+ is incorporated into carbon compounds: amides (amino acids) and ureides.

Nitrate reduction occurs mainly within the chloroplasts of green leaves, but can also occur within plastids of roots. Induction and the rate of nitrate uptake depend on the external nitrate concentration, light, pH, temperature, the concentration of other ions, anaerobic conditions, metabolic inhibitors, and biological genotypes. Since nitrate reductase contains Mo, Mo deficiency can cause N deficiency.

Nitrogen Storage

Seed storage proteins comprise 70% (up to 100% in some developing countries) of total intake of dietary protein by humans. It also provides the major protein source in the diet for nonruminant livestock. The amino acids in the leaves, produced from assimilated NO_3^- with energy and carbohydrates produced by photosynthesis, are transported to the embryo and the cotyledons via mass flux in phloem vessels of the leaf. The main transport forms of amino acids are: glutamine, asparagine, serine, alanine, glutamate, and aspartate. As a result, storage proteins are the products of the secretary pathway, which resides within the endomembrane system of the cell. In general, N assimilates available to developing grains are mainly used for the synthesis of proteins. These proteins then are accumulated and stored in specialized tissues such as the endosperm of cereals, other endospermic monocotyledons, or the cotyledons of the embryo for the pulse legumes and other nonendospermic dicotyledons.

Grains of cereal crops usually contain 7–19% protein while the seeds of legume crops contain up to 40% protein, in both cases on a dry matter basis. Tuber crops are rich in soluble carbohydrates and low in protein. For example, the crude protein concentration in sweet potato is twice that of potato (12.1% versus 5.4%). Thus, when tuber crops are used as human food or animal feed, they are a good source of energy, but require protein supplementation.

Almost all storage proteins in the seeds of major crops can be grouped into three categories according to their functions: (1) globulins (soluble in dilute saline solutions), the most common storage proteins, are present in all angiosperm seeds; (2) albumins (soluble in water); (3) prolamins (soluble in dilute alcohol) and restricted to the seeds of Gramineae (grass) family. This protein represents the main storage protein in cereals such as wheat (gliadins),

barley (hordeins), oat (globulins), rice (glutelins), rye (secalins), and maize (zeins). Both albumins and globulins have biological functions. This is particularly true of enzymes during seed germination. In most cases, storage proteins have no biological activity and only act as a source of N, sulfur, and carbon skeletons for the developing seed. Thus, storage proteins are not as evolutionarily constrained as those of other proteins, such as enzymes, although there is a requirement that proteins should be efficiently synthesized, packaged, and stored, and then remobilized during the process of seed germination.

Interactions between Nitrogen and Carbon Metabolism

The products of photosynthesis are the building blocks of agricultural production. From a production point of view, the efficiency of photosynthesis is mainly determined by the availability of light, CO_2, water, heat (temperature), and key elements in the soil, with N being the most likely to be limiting. Precipitation is outside management control in crop production systems, although irrigation may provide reliable water where water resources are available. Nitrogen application, including aspects such as quantity, timing, and method is part of most crop management regimes. Grain yield is largely a function of accumulation of photosynthetic assimilates. The interactions between carbon dioxide (CO_2) and nitrate assimilation and their dynamics are key elements of crop production. As a result, an adequate supply of N, its assimilation into amino acids (for which photosynthetically produced carbon compounds are required), and their availability for protein synthesis, are essential for metabolism.

Nitrate is reduced to NH_3 by NR and NIR using electrons from photosynthetic electron transport. The NH_3 is then converted into amino acids by the GS/GOGAT reaction (the main pathway by which plants convert ammonia into amino acids), and the "carbon-skeletons" are provided as organic acids derived from the tricarboxylic acid cycle. Carbohydrates for organic acid synthesis, ultimately from photosynthetic CO_2 assimilation, and ATP for the GS/GOGAT reaction are produced by photosynthesis and respiration. Thus, there is close interaction in the very earliest phases of N and carbon metabolism, both using light energy, with some 10% of the electron flux in photosynthesizing leaves used for N reduction.

During the last 4–6 decades grain yields of major field crops have increased ~2.5 fold, largely due to an increase in the production and storage of carbon in grains by efficient crop varieties and increased use of N fertilizer. Although large variations in grain protein concentrations exist among varieties within a species, an increase in yield has generally resulted in a slight to severe decrease in the protein/starch or oil ratio. For example, in the case of maize, the increase in the genetic-based yield potential after 1967 was, on average, accompanied by a decrease in the concentration of protein (~1.5%) and an increase in that of starch (~2%). In the case of soybean, genetic selection leading to a seed yield increase of $100\,kg\,ha^{-1}$, increased seed oil yield by $1\,kg\,ha^{-1}$, and decreased protein yield by $2-3\,kg\,ha^{-1}$. For wheat, an increase in yield of $\sim 2\,kg\,ha^{-1}$ led to a decrease in the protein concentration of more than 2% of the dry weight. Plant geneticists and breeders continually make efforts to break this relationship, hoping for increases in yield without decreases in quality.

Nitrogen and Environmental Health

Nitrate accumulation in plants occurs when the speed of nitrate uptake exceeds the rate of reduction and subsequent assimilation into amino acid and proteins for growth. A high nitrate accumulation in edible parts of plants consumed as vegetables is a potential health hazard. Although nitrate itself is not toxic, it can easily be reduced, internally, to the toxic compound nitrite. Reduction to nitrite in vegetables can occur postharvest as well as after ingestion, in saliva and in the gastrointestinal tract. One of the symptoms of nitrite toxicity is methemoglobinaemia, in which NO_2^- binds tightly to hemoglobin reducing the ability of the blood to carry oxygen and leading to respiratory dysfunction. Chronic nitrite toxicity may lead to the formation of carcinogenic nitrosamines. The frequency of gastric cancer could be reduced by avoiding high intake of nitrate.

According to the International Fertilizer Association, annual world consumption of N fertilizer is equivalent to ~83 million tons (Mt). North America accounts for 15% of this total world consumption. Nitrogen that is not taken up by plants may lead to gaseous loss to the atmosphere, or an increased level of nitrate in the soil. This nitrate is vulnerable to run off in surface water or leaching into groundwater, causing significant environmental pollution. High concentrations of NO_3^- in drinking water due to surface and ground water contamination can also lead to methemoglobinaemia.

Nitrous oxide (N_2O) is a greenhouse gas with a heat-trapping capacity that is ~310 times greater than that of CO_2. Since the last century N_2O emission has been increasing 0.3% $year^{-1}$. Emissions of N_2O from cultivated lands are estimated at 3.0–3.5 Mt N_2O-N $year^{-1}$. The bulk of current N_2O emissions

are caused mainly by the application of fertilizer N and biomass burning. When soils become anaerobic, or sometimes during the conversion of NH_4^+ to NO_3^-, N_2O is produced. N_2O escapes the soil as a gas and accumulates in the atmosphere where it is both an agent of stratospheric ozone destruction and a very potent greenhouse gas. High levels of soil organic matter and nitrate combined with low oxygen levels promote rapid denitrification. Increasing emissions of greenhouse gases are likely to accelerate global climate change. Average global surface temperature is expected to rise 0.6–2.5°C (33.1–36.5°F) in the next fifty years, and 1.4–5.8°C (34.5–42.4°F) in the next century.

Reducing the contamination of drinking water associated with excess application of inorganic fertilizer and manure in agriculture production is a high priority. There is an urgent need to develop new crop production systems that maximize N use efficiency and are less hazardous to the environment. However, the reduced application of fertilizers conflicts with the need for greater crop yields to feed rising world populations. Crop yields would drop to a very low level if N-fertilizer applications were to cease. Many countries that use substantial amounts of fertilizers and export agricultural produce would barely be able to feed their own population in the absence of N-fertilizer applications. To overcome the potentially dangerous social problems of food shortage, environmental degradation and pollution, agricultural yields per unit land area must be increased at the same time as dependence on applied fertilizers is decreased. Agriculture uses N fertilizer very inefficiently (even in developed countries), in part because other environmental conditions are often limiting. Thus, understanding the process of N uptake and assimilation, and mechanisms associated with increased N-use efficiency by crops would be a benefit not only in the context of environmental concerns but also crop quality. Consequently, selection of superior genotypes with efficient N-use and development of sustainable production systems for specific regions will solve or at least reduce the negative impact of fertilizer N use on the environment.

Conclusions and Prospects

Nitrogen is essential to the growth and reproduction of all plants, and animals. Improved understanding of N dynamics in the biosphere is of both economic and environmental importance in developing sustainable N management strategies for crop production. Absorption of nitrate and ammonium by plant roots is the primary pathway for the entry of N into our food chain. Nitrate and ammonium enter plants through the cell walls and root membranes. This mineral N has to be incorporated into carbon-nitrogen compounds in order to build cellular metabolites, especially protein. Some leguminous plants can convert atmospheric N to bio-available forms through a symbiotic relationship with specific soil bacteria. This rhizobia-legume symbiosis plays a major ecological and economical role on a global scale. A major recent achievement in understanding the rhizobia-legume symbiosis has been the characterization of signal molecules produced during initial communication between leguminous plants and N-fixing bacteria. The specific lipo-oligosaccharide (LCO) signal compounds, also called Nod factors, secreted by rhizobia, are considered to be a new class of growth regulator, affecting plant growth and development and ensuring the formation of N-fixing nodules. Consequently, a better understanding of the whole plant system, from genes, to plant-microbe relationships, to biomass production, partitioning and grain yield formation might achieve the long-term objective of improved crop N-use efficiency, leading to increased grain crop yield with reduced impact on the environment. For cereals and other nonleguminous grain crops, development of superior genotypes and sustainable production systems with efficient N use continues to be one of the major goals for plant geneticists, crop physiologists, agronomists, grain crop producers, environmental scientists, and policy makers.

NITROGEN METABOLISM

C A Atkins, The University of Western Australia, Crawley, WA, Australia

Introduction

The success that flowering plants enjoy is in no small way a consequence of the effectiveness of their seed as a perennating organ. The embryo is in a metabolically dormant state and is accompanied by a reserve of nutrients that can be mobilized on germination to support the activated meristems of the new plant. The diversity of composition exhibited by mature seeds reflects variation in the size and nature of this stored reserve. Some are high in carbohydrate, others in protein, and others in oil. Yet all are viable and are able to convert the reserves into translocatable solutes with a balance of C and N that supports the active root and shoot meristems before uptake from soil provides an alternative source of nutrients and before the seedling is autotrophic for C through photosynthesis. The reserves are fashioned from organic assimilates that supply C, N, and S through the long distance translocation channels of the vegetative structure of the plant.

Metabolism of N has been studied in a restricted range of seed types, mostly those of cereals, legumes, and oilseeds of agricultural importance and more recently in the model species *Arabidopsis thaliana*. Because of the high proportion of protein stored in legume seeds these have received most attention in this regard. However it is well to realize that plants produce an almost bewildering array of N-containing compounds, many of which are amino compounds that accumulate in seeds and are likely to impart unique nutritional, toxicological and pharmacological properties. Our understanding of this whole area in angiosperms is thus limited and fragmentary, and at this stage we must infer the commonality of processes that are so far only adequately documented for a few species.

Nitrogen Nutrition of Developing Seeds

Before considering seed nutrition it is useful to review the basic structural features of seeds and the consequences of this structure to solute import into and transfer within the component tissues of a seed as it develops. The outer seedcoat tissues are maternal while the endosperm and embryo within this coat are filial. There is no vascular connection between the two. Thus, whether stored reserves of the seed accumulate in the endosperm, the embryo, or associated tissues, in all cases solutes that supply C and N (assimilates) pass across an apoplastic compartment. It follows that in receiving translocated solutes before they pass to the embryo the seedcoat may regulate both the rate and nature of solute transfer.

Although developing seeds and their surrounding supporting structures may have the capacity for photosynthesis during early stages of development, this is limited. Consequently their major source of C is assimilates translocated in phloem and xylem. These are principally in phloem as sucrose, longer raffinose-based oligosaccharides, or in some species cyclitols, like mannitol and sorbitol. The same translocation streams supply N but typically phloem contains 10–20 times more N than xylem. However, even though both streams may carry a wide array of amino acids, as well as other N-solutes (e.g., proteins, nucleic acids, plant growth regulators), usually one or two low molecular weight organic compounds predominate. For many dicotyledonous species, including temperate legumes, these are the amides, glutamine and asparagine or their parent acids, glutamate, and aspartate, especially in cereals. In some species arginine, proline, or non-protein amino compounds like homoserine, ornithine, citrulline, canavanine, and putrescine predominate. In others, particularly nodulated legumes of tropical origin, the ureides, allantoin, and allantoic acid, account for almost all the N in xylem and a significant component in phloem-N. There are some very unusual N-solutes that translocate the bulk of N, for example djenkolic acid (two cysteines bridged at their S groups by a methylene) occurs at very significant levels in the xylem of some *Acacia* spp., and no doubt the plant kingdom employs many other forms of translocated N that have yet to be discovered. Thus protein synthesis in sink organs does not receive a mixture of amino acids that can be simply used to form protein, but rather a mixture in which just one or two solutes provide the bulk of N that has to be metabolized to generate the appropriate proportions of the 20 protein amino acids. In their passage from sites of phloem unloading to the embryo, N-solutes may be transiently stored, for example in the seedcoat, and are metabolized in highly specific ways within the tissue compartments they traverse.

There seems little doubt that almost all the N entering seeds is in an organic form. Although the literature records quite high levels of ammonium ion in both xylem and phloem, it is not likely that this is the norm and may, in many cases, be a consequence of hydrolysis of the amide groups of glutamine and asparagine during or subsequent to collection of vascular exudates. Xylem transports considerable quantities of nitrate from the root system to the major transpiring surfaces of the shoot but negligible quantities of this inorganic ion are transferred to phloem. As a result, fruit tissues and especially developing seeds are unlikely to receive significant levels of nitrate and consequently exhibit low or negligible capacity for its assimilation.

Early in legume fruit/seed development when a significant proportion of translocated N is delivered in xylem, the C : N ratio of incoming solutes is more narrow than that required by the developing tissues, and "excess" N is transiently stored. The endosperm in many dicotyledonous seeds accumulates a significant proportion of this N as ammonium ion and levels approaching 0.1 M have been recorded for periods of 3–4 weeks in white lupin (*Lupinus albus*) seeds. Although the ammonium is promptly reassimilated when the developing embryo expands to fill the endospermic apoplast, such high levels are normally regarded as extremely toxic and mechanisms that prevent this ammonium entering the embryo to any great extent must be functioning at this time. In pea (*Pisum sativum*), the major forms of accumulated N in the endosperm are homoserine, glutamine, and alanine, in cowpea (*Vigna unguiculata*) endosperm there is negligible ammonium ion but 30–55% of the N is histidine, while in chickpea (*Cicer arietinum*) ammonium and citrulline predominate. The significance of ammonium or other N solutes that accumulate to such high levels in endosperm when embryo development is characterized by cell division is unknown, but it is interesting to note that coconut endosperm ("milk"), used in pioneering studies of plant cell and tissue culture, contains high concentrations of N, including ammonium ion, along with plant growth regulators.

A positive correlation has been established between rates of ammonia emission (i.e., N loss) and ammonium concentration in leaves. There are no emission data available for developing seeds/fruits, but given the high levels of ammonium ion that may accumulate in liquid endosperm it seems possible that transient periods of N loss occur due to its volatilization. It is perhaps not too surprising then that the highest rates of ammonia emission in barley occur during grain filling.

The mix of solutes in phloem is not constant during reproductive growth, the C : N ratio changing to more closely match the C and N requirements of the developing seed. In white lupin, sucrose levels in phloem decline progressively after anthesis while the concentration of amino compounds increases, almost doubling over the period of grain filling. This pattern of change is consistent with a declining rate of photosynthesis and increasing senescence of leaves, with release of protein-N as amino compounds, during reproductive development. However, further studies with lupin have shown that in fact the phloem N level also increases to narrow the C : N ratio as a consequence of solute specific mechanisms that achieve an enrichment of phloem with asparagine as the translocation stream passes through stem segments immediately before entering the inflorescence. Similar specific exchanges of amino acids have also been found for developing cowpea fruits/seeds. The precise tissue or cellular site where these transfer mechanisms act and the molecular basis for their regulation is unknown but a role for transfer cells has been inferred.

The developing seed is supported on or within fruiting structures that not only bear the vasculature which brings the translocation streams to the seed but which serve also as intermediate sites for metabolism and transient accumulation of nutrients, including N. For example, in the period from anthesis to 11 days after anthesis, in cowpea fruits 21 mg N enters in phloem and 17 mg N in xylem. Of this N less than half (15 mg) reaches the developing embryo and endosperm, the rest is sequestered into the pod wall (16 mg) and the testa (7 mg). Importantly, however, the incoming N-solutes are metabolized extensively before being transferred to the embryo. At this early stage of development xylem-N is ~70% ureide and phloem-N ~20% ureide, but ureides account for less than 20% in the podwall and testa and no more than 2% of soluble-N in the liquid endosperm or embryo. Later in development (12–22 days after anthesis) phloem accounts for 80% of N entering the fruit and, although the ureide level is low, ureide-N accumulates preferentially in the seedcoat. Despite this enrichment literally no ureide is transferred to the apoplast surrounding the embryo. Rather, ureide-N is converted to glutamine and this is the major source of N for protein synthesis. Similar observations have been made for soybean, another plant that translocates significant levels of ureide-N in xylem and to a lesser extent in phloem.

In pea a major N-solute entering the seedcoat in phloem is homoserine and, although this may accumulate transiently in endosperm, most is converted to threonine and glutamine in the seedcoat during embryo expansion. Even in species that have an asparagine-rich phloem stream reaching the seedcoats,

a significant proportion of asparagine-N is converted to glutamine-N during passage to the apoplast and embryo. Whether this apparent preference for N as glutamine in the embryo's nutrition reflects some metabolic requirement or the specificity of transporters involved in transferring solutes across tissue compartments of the seed has yet to be clearly resolved. In maize the endosperm of the developing kernel supplied assimilates through the pedicel and even though the major phloem N-solute is aspartate this is largely metabolized with its N being transferred to glutamine. The maize pedicel expresses a unique cytosolic form of glutamine synthetase, GS_{p1}, which is developmentally regulated, increasing as storage protein synthesis increases. Glutamine is the major amino acid released from the pedicel to the apoplast surrounding the endosperm and a transporter expressed in the basal endosperm transfer cells apparently enhances its uptake. Thus specificity of both metabolism and transport combine to ensure that a preferred N-solute reaches the embryo tissues.

Transport of N-Solutes within Seeds

Rates at which solutes that supply C and N to the embryo are transported are likely to contribute to determining the potential accumulation of assimilates or "sink strength" of seeds and consequently grain yield and harvest index. Studies with four cultivars of bean (*Phaseolus vulgaris*) that differed in their rates of seed growth found that although sink size, as assessed by surface area and volume of cotyledons, were major determinates of growth rate, the rate of transfer of dry matter was also a contributing factor. Not surprisingly, maximal sucrose fluxes into cotyledons were positively correlated with levels of expression of the sucrose/H^+ symporter and accompanying H^+-ATPase in the dermal cells facing the apoplast between the cotyledons and the seedcoat. Specifically in relation to N nutrition, activity of amino acid transporters has been suggested to regulate the rate of seed protein synthesis. Although most research into solute unloading from phloem and transport within developing seeds has involved sucrose, some of the amino acid transporters expressed in seed tissues have been identified and their location studied in relation to likely function.

In pea, two cDNA clones (PsAAP1 and 2) belonging to the AAP (amino acid permease) family of H^+/amino acid co-transporters have been isolated from cotyledons. Like the sucrose transporter, PsAAP1 is highly expressed in specialized epidermal transfer cells abutting the seedcoat and shows broad specificity, mediating transport of acidic, neutral, and basic amino acids. Similar broad-spectrum members of the AAP family have been described for developing *Arabidopsis* and castor bean seeds. In *Arabidopsis* AtAAP1 is localized to endosperm and cotyledons while AtAAP2 is restricted to the vasculature of siliques and the funiculus. Thus, AtAAP2 is thought to mediate exchange of amino acids from xylem to phloem. Such an exchange has been identified as a specific asparagine transfer in the upper stem segments and raceme of lupin to enrich phloem with N, narrowing the C : N ratio to match more closely seed demands for these commodities.

The broad substrate specificity found for most plant amino acid transporters does not conflict with the idea that translocated N is characterized by just one or two amino acids. Most of the amino acid transporters from plants have been characterized by yeast mutant complementation or functional analysis in *Xenopus* oocyte assays and specificity *in vivo* may be quite different. Indeed, differences in affinity for amino acid species have been described. Furthermore, specific transporters are likely to be found when more extensive genomic data is available for a wider range of plants.

As noted above seed tissues produce and may transiently accumulate significant amounts of ammonium ion. It appears that this is a feature of their metabolism throughout development, raising the question of transport mechanisms for the ion within seed tissues. Preliminary data indicates that genes homologous to the high affinity ammonium transporter family (AMT), *AtAMT1* from *Arabidopsis*, are not expressed in the seedcoat and cotyledons of developing lupin seeds. However, the recently described high affinity *AMT2* transporter gene is expressed in *Arabidopsis* siliques and this may be the transporter that functions in seeds. In view of the widely diverse levels of ammonium that form in seed tissues at different stages of development it seems likely that other transporters/channels with quite different kinetic features are also involved.

The *Arabidopsis* genome has revealed transporters for other types of N-solute that are expressed and could have significant roles in seed metabolism. These include oligopeptide transporters, such as AtPTR2-B, that might be responsible for the movement of peptides released from storage proteins during germination to new meristems or in the transport of signal peptides from sites of synthesis to sites of action. The possible importance of peptide transport in seed development was highlighted in a study where antisense lines for *AtPTR2-B* were generated in *Arabidopsis*. The transgenic plants showed normal silique development but formed fewer, larger seeds than controls. Specifically about half of the embryos were arrested at an early stage of their development,

suggesting peptide transport was essential for N nutrition at this time or that transfer of some bioactive peptide, essential for embryogenesis, was limiting.

Plants also express high affinity transporters specific for purines and purine derivatives (PUPs) including bases, nucleosides, purine alkaloids, and cytokinins. Northern analysis for *AtPUP1* in *Arabidopsis* has however shown only a low level of expression in developing siliques compared to other tissues and their functional significance in seed development or in the mobilization of N during germination remains to be established.

A novel superfamily of transporters has recently been described for allantoin and other oxidized derivatives of heterocyclic N solutes in *Arabidopsis*. In view of the predominance of ureide-N in translocation streams serving developing fruits in certain tropical legume species, but with the metabolic requirement that ureide-N is not transferred from the maternal tissue to the embryo, it will be interesting to see whether or not fruit and seed tissues express these transporters. Enzymes of purine oxidation (urate oxidase and allantoinase) have been demonstrated at elevated levels during germination of a number of seeds, and it has been inferred that purines are released due to intense nucleic acid hydrolysis. If indeed allantoin provides a supplementary source of translocated N to the newly formed root and shoot apices then the novel allantoin transporters may be important in phloem loading at this time.

Primary N Metabolism

The primary pathways of N metabolism in seeds are the reactions that utilize incoming N-solutes to form the 20 protein amino acids. As noted above N-solutes translocated to tissues surrounding a developing seed or to the embryo itself are characterized by one or two predominant compounds. Among these asparagine and glutamine appear to be the most common. Although some incoming asparagine is incorporated directly into seed protein the majority is metabolized (in white lupin more than 80% over 13 weeks of development). Supplying ^{15}N (amide)-labeled asparagine to developing lupin fruits in phloem resulted in label being recovered in 15 amino acids following hydrolysis of seed protein. In addition to asparagine, glutamine, aspartate, and glutamate, those labeled included arginine and histidine, those derived from pyruvate (alanine, leucine and valine) and 3-phosphoglycerate (glycine and serine), those of the aspartate family (lysine and isoleucine) as well as aromatic amino acids (tyrosine and phenylalanine). Clearly seeds express all the major pathways for synthesis of protein amino acids.

There are two potential pathways releasing asparagine-N to amino acid synthesis. Hydrolysis of the amide-group by asparaginase produces ammonia and aspartate, the latter providing an amino donor to the many aminotransferases (AT) that have been detected in seeds. The second pathway utilizes an asparagine-AT that transfers the amino group to glyoxylate forming glycine and 2-oxosuccinamic acid. The acid is reduced to 2-hydroxysuccinamate and deamidated to ammonia and malate. Although both potential pathways are expressed in developing pea fruits, asparagine-AT is largely confined to pod tissue and is very low in developing seeds. Asparaginase on the other hand is expressed at high levels in seedcoats early in development, transiently in endosperm and in filling cotyledons of legume seeds. The same could be said for predominant non-amino acid solutes like the ureides. Although there are a number of enzymic routes for the degradation of allantoin that are expressed in different plants, differing even between cultivars, the N is released as ammonia. Thus reassimilation of ammonia is a major activity of seed tissues whether in the seedcoat, endosperm, or the components of the embryo. Not surprisingly, both glutamine synthetase (GS) and glutamate synthase (GOGAT) activities are expressed in seed tissues, providing a high affinity utilization mechanism for ammonia that is likely to function in reassimilation throughout seed development. Seeds express glutamate dehydrogenase (GDH) activity and this may also participate in reassimilation. While the role of GDH has been the subject of considerable debate and conflicting opinion the consensus view that has emerged for most tissues appears to be one of oxidation of glutamate rather than synthesis. However, the very high concentrations of ammonium ion that form transiently in the endosperm of some seeds would be kinetically favorable for GDH to function, for a short while at least, in its assimilation.

Among the protein amino acids that are synthesized largely *in situ* to meet the needs of seed storage protein accumulation are those of the aspartate family; namely lysine, threonine, isoleucine, and methionine. Not surprisingly expression of the first committed step in the aspartate pathway, catalysed by a bifunctional aspartate kinase (AK)-homoserine dehydrogenase (HSDH) in *Arabidopsis*, is coincident with storage protein synthesis in the embryo. Cereals are deficient in lysine and in some, threonine and tryptophan, while legume seeds are poor sources of S-amino acids, particularly methionine. As a consequence there has been considerable research into regulation of the pathway for these "essential" amino acids. There have also been numerous attempts to

exploit this knowledge to enhance the nutritional and/or processing qualities of both cereal and pulse grains. AK activity is subject to feedback inhibition by pathway products, specifically lysine or threonine. However, in the high lysine *opaque*-2 mutants of maize very significant levels of the aspartate family accumulate as a pool of free amino acids in the mature endosperm. Accumulation results in part from lysine degradation being compromized, because lysine-ketoglutarate reductase activity is suppressed, but other studies have identified changes in sensitivity of the monofunctional AK (Ask2) to feedback regulation by lysine as a major genetic determinant of free amino acid content. In a mapping population with the mutant Ask2 was a good candidate gene for a quantitative trait locus (QTL) affecting free amino acid content in the harvested grain. Dihydropicolinate synthase (DHDPS) converts the product of AK (aspartate 4 semialdehyde) to an intermediate in lysine synthesis and is also subject to feedback inhibition by lysine during seed development.

Specific features of C metabolism within the developing seed are required to accommodate some aspects of amino acid synthesis. Phosphoenolpyruvate carboxykinase (PEPCK) is present in a wide range of developing seeds. In grape seeds, PEPCK is expressed in the inner layer of the seedcoat, in the chalaza and in cells at the boundary of the storage tissue; expression coinciding with maximum deposition of storage reserves. Feeding asparagine to developing grape seeds caused a strong induction of PEPCK indicating that the enzyme functions in the metabolism of N-solutes after unloading from phloem. These data are consistent with an anaplerotic role for PEPCK in supplying acetyl-CoA when the TCA cycle is involved in the interconversion of C skeletons for 4C and 5C amino acids.

Because seeds are formed within enclosing structures that limit gas exchange the concentrations of respired CO_2 within the structures may build up to quite high levels and refixation of some of this C is achieved through RubisCO (Ribulose bis P carboxylase/oxygenase) and especially PEP carboxylase. In lupin embryos some of this refixed C is incorporated in sugars and TCA cycle intermediates (malate, isocitrate, and citrate), but as much as one-third provides C for a range of amino acids, principally alanine, aspartate, and serine, but also glutamate, glutamine, asparagine, glycine, valine, leucine, and isoleucine. In *Vicia faba* PEP carboxylase is up-regulated in cotyledons during grain filling. Again this suggests an anaplerotic role for the provision of 5C skeletons to the TCA cycle functioning in amino acid synthesis in an intensely respiring tissue.

Synthesis of Stored N Reserves in Seeds

The major dietary sources of plant protein are seeds of cereals and legumes. Legumes and some oilseeds typically contain 30–50% dry weight as protein while cereals are lower, ~10%. The "storage" proteins constitute up to 90% of the seed's protein at maturity and as a consequence it is this group that largely determines the nutritional and processing qualities of grain. Features of the synthesis, localization, and properties of the major storage proteins have been reviewed extensively and, more recently, details of the regulatory mechanisms that determine their synthesis in response to changes in plant nutrition and environmental conditions are being revealed.

While most of the incoming N is used for protein synthesis, seeds may also accumulate quite a significant pool of free protein amino acids that persists to maturation and constitutes a "store" at maturity. The amides glutamine and asparagine are common constituents of this soluble-N pool but other amino acids may predominate in some species.

One of these soluble reserves is arginine. In soybean arginine is synthesized in developing cotyledons as well as being supplied from the seedcoat to the embryo through the apoplast. Its accumulation to more than 60% of the free amino acid pool apparently occurs because arginase is not expressed in the embryo. The accumulation of lysine and other amino acids of the aspartate family in maize endosperm was noted above and doubtless there are numerous other examples that occur in nature.

Seeds accumulate significant quantities of nonprotein amino acids. Some of these, such as homoserine, are intermediates in the synthesis of the 20 protein amino acids while others are accumulated as end products of metabolism. Some, such as the arginine analogue canavanine, are highly toxic to insects and other potential herbivores apparently serving to protect the developing or mature grain. Canavanine can reach levels that are 6% of the dry weight in the seeds of *Canavalia ensiformis* and so represent a significant stored reserve of N. Mature groundnut (*Arachis hypogea*) seeds contain high levels of γ-methylene-glutamine that is mobilized to the developing seedling following germination but is not metabolized to any great extent, apparently accumulating again in the next generation of seed.

There are hundreds of nonprotein amino and imino acids formed by plants with the overwhelming majority of these accumulated in seeds. Many of these occur in sufficient amounts that they could be construed as a stored reserve but the physiological and biochemical studies to confirm this role have yet to be undertaken.

Mobilization of N Reserves in Germinating Seeds

While the N reserves in seeds are principally in the form of storage proteins, as germination proceeds N from nucleic acids or metabolic proteins that might have been formed before dehydration or subsequently following imbibition is also available. The possibility that allantoin is formed from nucleic acid catabolism has been indicated earlier. Additionally seeds mature with what can be a significant soluble N pool and this appears to have a specialized role in the first few hours/days of germination when the newly activated meristems of the embryo begin to grow rapidly.

Arginine has been recognized as a common constituent that fulfils this role. Its accumulation as the seed matures results from suppression of an enzyme, arginase, which would normally catabolize the amino acid. However, within a day after imbibition arginase transcript level and activity increase sharply in the cotyledons to release urea and, as a result of urease activity, ammonium ion for reassimilation and translocation to the new meristems. It is likely that the translocated N-solute at this time is glutamine. Thus arginine is a "compact" form of stored N (C:N ratio of 1.5) that provides an almost instant N source, and is no doubt used in this role in a wide range of species (e.g., pumpkin and pea seeds). Whether other soluble N-compounds that accumulate in maturing seeds function as initial sources of N for germination is not known.

Ammonia released from oxidation of free and mobilized amino acids can account for 50% of the N made available during germination of *Arabidopsis* seeds indicating, as during seed development, a central role for GS/GOGAT in reassimilation. QTLs for enhanced germination efficiency in maize have been identified that are co-localized with two of the GS1 (cytosolic forms of glutamine synthetase) structural genes, *gln3* and *gln4*, emphasizing the importance of ammonia reassimilation in regulating the germination process. Such markers offer the potential to breed for complex traits related to seed N metabolism in grain improvement program.

Future Prospects

Despite the wealth of knowledge about the composition of seeds and the nature of their stored reserves, factors that determine which reserves are formed and stored and the roles of environmental cues in these processes have yet to be established. Clearly there is tissue-specific and temporal expression of genes that encode biosynthetic enzymes but the nature of the mechanisms that integrate metabolism so that stored N-reserves are generated to maximize the available resources of C, N, and S need to be resolved. Although functional genomic or proteomic analyses have been applied to developing seed tissue they have yet to reveal new information about more detailed aspects of the pathways and regulation of N metabolism and transport. As genomic analysis is extended to a wider range of plants this information will become available providing new tools for both understanding and manipulating grain development. Significant changes to grain composition through selection from germplasm collections, conventional breeding and the exploitation of direct genetic engineering will be an ongoing area for research as novel, more nutritious and health promoting food ingredients are sought. Because plants engage in a bewildering diversity of N metabolic end products, many of which accumulate in seeds, it is important that critical studies of N metabolism are extended beyond the handful of species for which information is currently available.

Introduction

Noodles form a diverse category of foods that utilize starchy staple crops throughout Asia. Most are in the form of long strips so that traditionally noodles have often been served during special celebrations to symbolize "long life." Today, noodles are consumed as part of ordinary daily meals, snacks, or salads and may be eaten hot or cold. They can be cooked in a variety of ways such as boiling, steaming, stir frying, and deep frying. Noodles may be broadly classified into two general types, i.e., wheat and nonwheat noodles. "Nonwheat noodles" comprise starch noodles (e.g., those from sweet potato) and those from flour (meal) of crops such as maize or rice. Some grains can be used for either starch or flour noodles (e.g., rice). Wheat flour is a unique material, because a simple addition of water coupled with energy input through mixing enables the formation of dough that can be kneaded and stretched to make noodle sheets and strips. This is due to the properties of its unique protein (gluten) that is mainly responsible for wheat noodle structure, although recent studies show that wheat starch properties also contribute to noodle texture. As nonwheat raw materials do not contain gluten, another mechanism of structure formation is utilized to produce noodle sheets and strips, based on the possession of appropriate starch functionality and its manipulation during processing. These products are called nonwheat noodles or often more appropriately starch noodles. Examples include noodle sheets, strips, and threads from flour and starch of cereals, legume starches, and root crop starches. These products are either sold fresh or dried for greater storage stability. The method by which different botanical source substrates are processed into noodles is discussed in this article. The variety of these Asian products is presented in Table 1, listing the regional names, English equivalents, the countries where they are produced, and their outstanding characteristics and uses. These products are generally bland tasting but readily absorb flavors from other ingredients with which they are cooked. Starch noodles are commercially produced from cereals such as rice and maize and from root crops such as potato (*Solanum tuberosum*), canna (*Canna edulis*), arrowroot (*Maranta arundinacea*), cassava (*Manihot esculenta*), and sweet potato (*Ipomea batatas*) in many Asian countries.

Types of Asian Starch Noodles

Rice noodles come in a variety of forms such as thin threads that may be bundled or packed in a compact block (Figure 1a). They are also produced as well-separated rice sticks that vary in diameter and are generally straight cylindrical rods (Figure 1b). There are also flat noodles or ribbons that are well separated and packed as folded bundles. This noodle is commonly used in Vietnamese soups with meat and vegetables (Figure 2a). Distinct characteristics of dried rice noodles are their off-white color, slight opacity, and brittleness of the raw noodles. If enough caution is not taken during packaging and transport, the noodles will easily be broken.

In The Philippines, common starch noodles are almost entirely produced from maize starch, which has been found to be a good substitute for rice, the traditional substrate. The consistency of maize starch in terms of quality, as well as supply and price, has driven this gradual shift to reduced use of rice. It is used as the base for the Philippine "pancit palabok," which is boiled noodles served with a traditional sauce and toppings (Figure 2b). Instant rice noodles in clear soups are found in many Asian supermarkets and come in thread and ribbon forms (Figure 1c). They are either boiled in water or soaked in boiling

Table 1 Different types of starch noodles in Asia

Substrate	*English name or equivalent*	*Country*	*Regional name*	*Special characteristics*
Rice	Rice vermicelli	China, Malaysia, Philippines Vietnam, Thailand	*mei fun, kuey teow, Bijon, bihoon, banh hoi, sen lek, sen mee*	Soak the dried noodles in hot water to soften; thin noodles used for soups, stir fries, salad
	Rice sticks	Malaysia Vietnam	*Laksa, to banh pho*	Soften them in hot water; for soups, salad and spring rolls
	Flat rice noodles; ribbon noodles	Thailand	*Banh pho; junta boon; chanta boon*	
		China	*Ho fun, sha he fen*	
	Rice flake noodles	Malaysia	*kuay chap, banh uot mien*	Shaped like tortilla chips; soften in hot water
Mung bean	Bean threads	China	*Baifun, Sai*	Soups, stir-fries, salads, desserts, and drinks
	Translucent, silver, shining	Vietnam, Indonesia, Thailand Philippines	*fun, soo hoon, su, un, sotanghon*	
	Transparent	China	*Fansi, fun see*	Flavorless, but readily absorb flavors
	Glass, crystal noodles	Japan, Thailand, Indonesia	*Harusame, woo sen, boon tau, pekjysan, tanghoon*	Soak until soft
	Mung bean, rice		*Tientsin fen pi*	
Cassava	Tapioca stick	Thailand	*hu tieu bot loc*	
Sweet potato	Sweet potato vermicelli	Korea	*Dangmyun, tangmyun*	Soak in hot water before use
Maize starch	Maize starch noodles	Philippines	*Pancit bihon, luglug*	Wash with water before use, stir fry
Buckwheat (mixed with noodles wheat flour)	Buckwheat noodles	Japan	*Soba, naeng myun*	Buckwheat flour and potato starch; may be served hot or cold
	Buckwheat noodles	Japan	*cha soba*	With green tea
	Buckwheat noodles	Japan	*nama, hashiwari*	With greater amount of buckwheat flour
	Buckwheat noodles	Japan	*yaki, chuka*	With high fat content

water for 3 min before being served and are offered with assorted flavors of soup base such as chicken, seafood, and beef. They may also be conveniently packed in cups to which boiling water is poured and can be directly consumed after a few minutes (Figure 1e).

Another type of noodles is produced from the legume, mung bean (*Vigna radiata*) (Figure 1d). These noodles are much whiter, and usually thinner in diameter than rice noodles, very glossy, clear and with high tensile strength both in the raw and cooked form. The strands are well separated, bundled neatly, and do not break easily. Another difference between rice noodles and bean thread noodles is the cooking instructions that come in the package. Rice noodles are usually provided with detailed instructions on how the product is to be prepared for cooking, such as soaking, boiling, and washing in cold/hot water before it is used in soup or stir-fried dishes. Emphasis is given to the time required so that a desired textural quality in the cooked product is attained. In contrast, mung bean noodles are normally

Figure 1 Different types of Asian noodles: (a) thin rice vermicelli; (b) rice sticks; (c) instant vermicelli; (d) bean noodles; (e) instant starch noodles-in-a-cup; and (f) buckwheat noodles.

not provided with these instructions, because they can withstand long soaking and boiling times without adverse effects on the characteristic texture.

Another variant of starch noodles are the wrappers used in many food preparations. Steamed Chinese "dimsum" are normally wrapped in wheat flour dough sheets but may also be wrapped in starch sheets made from wheat and cassava. These provide a nearly transparent skin that shows the colorful mixture of the vegetable and meat filling of the product. These

Figure 2 Prepared dishes and the starch noodle/wrapper used: (a) rice flat noodles used in beef soup; (b) maize starch noodles in pancit palabok; and (c) rice paper used for steamed spring rolls.

wrappers may also be mixed with vegetable juices from spinach or carrots to give a dimsum dishes diverse natural colors. Wraps or sheets may also be sold in the dried form and used as spring roll wrappers. A variant is shown in Figure 2c, a Vietnamese steamed spring roll with mixed vegetable and meat filling wrapped in round rice paper.

Noodle Processing

The general procedure by which starch noodles are made is presented in Figure 3. A portion of the flour or starch is gelatinized to serve as binder which allows formation of dough or batter which may be extruded or sheeted and further molded into the desired shape. The variations possible in each step in different products are presented in the following sections.

Substrates Used for Starch Noodles

The generally considered best substrate for starch noodles is from the legume, mung bean (*Vigna radiata*), which normally has high amylose content (greater than 30%). The eating and cooking qualities of mung bean noodles are usually the benchmark for high standards when working on experimental starch substrates and process parameters for starch noodles. Aside from its tensile strength and chewiness, bean noodles are also known for clarity and gloss not observed in noodles from other substrates. This characteristic is the reason why they are referred to as "spring rain," "invisible," "transparent," or "glass" noodles. It also has high tensile strength both in raw and cooked form. Legume starches generally exhibit a characteristic type C Brabender pasting profile characterized by the absence of peak and breakdown, and high hot paste stability and setback, similar to

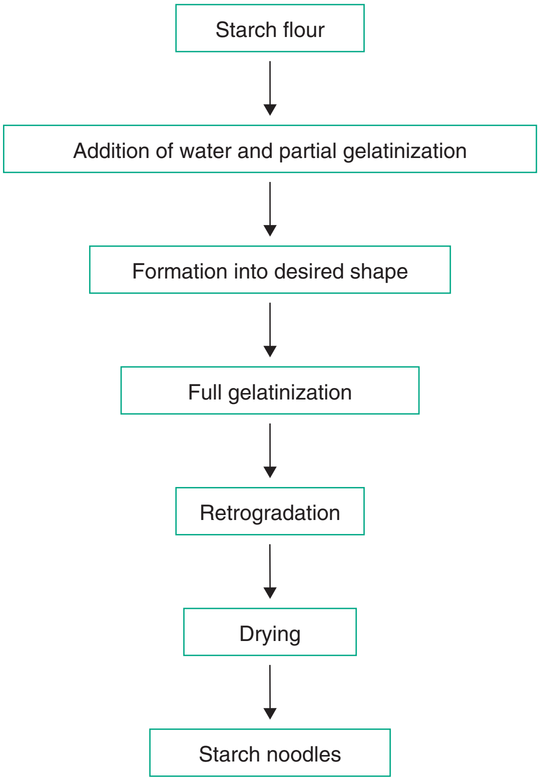

Figure 3 Schematic flow diagram for starch noodle production.

cross-linked starches. Studies on noodles from different cereal and root crops have shown that textural quality of noodles produced is significantly correlated to the pasting profile determined using a visco-amylograph. The pasting profile characterized by high hot paste stability and high setback has been used by several workers as screening criteria for evaluation of different substrates and starch modification processes for suitability for noodles.

In The Philippines, as maize starch has become a common replacement for rice in starch noodles, initial process steps involving soaking, washing, and wet milling of rice grains have been eliminated. It has simplified the process, reduced costs, and also produced noodles with consistent quality in terms of color, surface smoothness, and texture. Although noodles from yellow maize make distinctly yellowish noodles as compared to white maize, this difference does not seem to adversely affect most purchase decisions of consumers. The use of starch (instead of rice flour) offers additional stability from rancidity. It is also common practice to add cassava starch to improve texture of rice and maize starch noodles. Fresh starch noodles or wrappers are likewise prepared from a composite of wheat starch and cassava starches to attain a characteristic translucency and texture not possible when the starches are used individually in the formulation. Generally, blending of starches serves to improve texture which may be reflected as increased strength and elasticity imparted to starch sheets during processing. This makes the sheet less vulnerable to breakage and consequently reduces production losses. Another common recommended noodle improver is "konjac" flour, composed mainly of glucomannan and extracted from elephant's foot yam (*Amorphophallus* sp.). It may be added at the rate of 3–10% of starch, and its addition not only improves texture but also increases the soluble fiber content of the product.

A traditional product from composite flour with wheat is buckwheat noodles (Figure 1f). Its structure is partially dependent on the wheat flour component. It is brownish in color and can be found in both the dry and fresh form and can be served hot or cold. Buckwheat noodles are known in Japanese as "soba." This refers to long and thin brownish noodles made from a composite of buckwheat flour and wheat flour, the ratio of which varies according to the type of the product. The most common buckwheat noodles combine 60–70 parts buckwheat to 30–40 parts wheat flour, to which 45–48 parts water is added. Korean buckwheat noodles may include potato starch. Other formulations may include the addition of green tea that imparts a characteristic color.

Partial Gelatinization of Moist Starch

In the preparation of rice noodle, the grains are soaked overnight, washed, and wet-milled to a fine consistency, after which excess water is drained. When purified starch is used as substrate such as in the case of maize, potato, and sweet potato, water is added to the dry starch to make ~20% moisture content (Figures 5a and 6a). This initial moisture enables mixing with minimal lumpiness that facilitates easy addition of more water. For rice and maize noodles, the dough is formed into fist-sized balls and cooked in boiling water for ~30 min. The outer layer is cooked in the process but the inner portion is left uncooked. A kneading process is employed to fully disperse the gelatinized starch in the uncooked portion to produce noodle strands that do not readily break during extrusion.

In the preparation of buckwheat noodles, the most common process involves mixing buckwheat flour into wheat flour, to which water is added, the amount depending on the protein content of the mixture. The flour is mixed in a circular motion with gradual addition of water. The binding capacity of the flour is greatly improved by using boiling water during the initial mixing stages which gelatinizes the buckwheat flour starch.

For jelly noodles from sweet potato and potato, a batter with appropriate flow characteristics is required to enable smooth application on to a metal plate or cloth canvas to form a sheet. The metal sheet conveyor is always kept clean so that the smooth sheet is peeled off easily. The addition of hot water of ~70–80°C with simultaneous mixing enables partial gelatinization and development of right viscosity and smoothness (Figure 5b). In a similar manner, Chinese dimsum wrappers from starches are prepared by adding boiling water to wheat starch and cassava starch to enable the formation of dough which can be formed into a ball and rolled thin to a circular sheet used to enclose the filling, otherwise the sheet breaks easily when folded.

Shape Formation

In rice and maize starch noodles, smooth balls are made from the kneaded dough and loaded into a cylindrical tube holder ready for extrusion by a hydraulic press that forces the dough through a die with specified opening corresponding to the noodle diameter (Figures 4b–4d). For flat noodles, the cutting step is done after sheet formation that is set through gelatinization. In fresh-noodle processing, the cutting edge is heavily coated with oil to prevent starch sheet and noodles from sticking to metal-cutting surfaces. When dried flat noodles are prepared, the sheet undergoes a short drying process before a cutting step is employed. The process may involve a drying cabinet with air drying/tempering as shown in Figures 5d and 5e, in the production of potato jelly sheet noodles.

Dimsum wrappers are formed by carefully picking up the flattened soft pliable circular dough, folding 3–5 times on one side of the circle, pinching to keep the folds in place, putting a tablespoon of filling into the dough circle and sealing tightly with another pinch. For dried starch wrappers, the shape is attained when batter is poured on to a shaped mold normally a round shallow container. Rice spring roll wrapper usually has a delicate weave design that it picks up from the bamboo tray on which it was molded and dried. A Vietnamese dish uses this rice paper as wrapper for steamed or fried spring roll (Figure 2c).

The different preparation methods for starch noodles are determined to a great extent by the flow characteristics of the starch dough and are reflected in the finished product. It was observed in some studies that the starch dough becomes more cohesive when phosphorylated cassava starch is added to potato starch resulting in thicker noodle strands even when using the same die opening, compared to use of pure mung bean, sweet potato, or potato starches. Even at similar moisture content (~50%), for starch dough in which gelatinized starch is used as binder, different starches exhibit different flow characteristics so that a different extrusion or sheeting condition may be needed. In dried rice noodle production, a hydraulic press extruder is used while for sweet potato noodle production, an open mechanically driven screw-type extruder is used (Figure 5c). Reports on different substrates vary in the proportion of 1 : 1 to 1 : 3 (w/w) uncooked and gelatinized starch and moisture content which range from 45% to 60%. Lower and higher ratios of gelatinized starch produced slurry that was either too dry or soft to extrude. However, a much lower amount of gelatinized starch binder (~5–7%) has been used successfully in the preparation of mung bean noodles. This may be attributed to the difference in the degree of gelatinization of binder, extrusion conditions employed, the unique starch properties of substrate being used, and/or the additive or improver applied. Indeed, the process of making starch noodles remains an art based on experience in the handling of a particular substrate.

Full Gelatinization of Shaped Dough

The shaped noodles or sheet is fully gelatinized by either boiling or steaming. In rice noodles, the noodle strands may be extruded directly into boiling water in a cooking vat for 2–5 min or steamed on trays in steaming chambers for 15–20 min. Once the extruded noodles are dropped into boiling water, they are removed when sufficiently cooked or when strands begin to float on the surface (Figure 4d). This is due to the change in density of the noodle strand as it is cooked or gelatinized. Uncooked starch granules have a relatively high density, ~1.5 g cm^{-3}, so that uncooked noodles settle directly to the bottom of the cooking container; but as they gelatinize, starch granules swell as they absorb more water and consequently float on the surface of boiling water. The extruded noodles can also be steamed in a conveyor for 15 min at 120°C. Full gelatinization of the extruded noodles serves to set noodle structure and improve texture and flavor on cooking. Degree of gelatinization of steamed extruded rice noodles is reported to be from 65% to 70%, with the surface ~98% gelatinized and the core only 55% gelatinized.

For flat noodles, the starch sheet is steamed through the application of heat under the metal or canvas conveyor which moves over the heating/steaming components. In effect, the speed by which the sheet moves sets the cooking time. In the processing of canna starch noodles in Vietnam, the steam sheeting of canna starch dough is followed by a stretching step

not found in rice or mung bean/sweetpotato jelly sheet noodles. For Chinese dimsum, cooking enables not only setting the wrapper shape but it also cooks the vegetable and meat fillings.

Retrogradation

In the production of starch noodles, processes are employed to enhance retrogradation, such as the

Figure 5 Potato starch noodles production showing: (a) mixing starch batter; (b) application of batter on a metal sheet; (c) cooked sheet peeled off from metal sheet; (d) drying starch sheet; (e) tempering of starch sheet; (f) sheets in rollers; (g) cutting; (h) drying; and (i) potato noodles (Changchun, People's Republic of China).

low-temperature conditioning step applied after the gelatinization of the noodle strands or sheets. Retrogradation is the process that finally sets the noodle structure that can withstand normal cooking temperatures in soups and stir-fried meat and vegetable dishes. This may involve freezing and thawing as in mung bean noodles, or a simple washing in cold water and tempering as in rice, potato, and sweet potato noodles at room temperature (Figures 5e and 6g). It is interesting to note that in village level production of sweet potato noodles, the conditioning stage is attained naturally since processing is an annual

activity during the cold months in October or November when night temperature in Sichuan and Shandong, China, drops to 0–5°C. After an overnight conditioning, the noodles are separated and allowed to dry under the sun and drying is further enhanced by the low relative humidity which normally drops to ~50% during this time of the year. In many production systems in Asia, favorable conditions

for retrogradation have to be provided artificially through appropriately designed processing equipment and facilities to ensure consistent quality.

Starch is made up of two molecular forms, the unbranched glucose polymer, amylose, and the branched glucose component, amylopectin. Earlier findings revealed that amylose crystallization in the retrograded B-form kept the structure intact in rice noodles and mung bean starch noodles. The following discussion deals with the retrogradation process as it relates to starch noodle processing and the formation of a thermally stable structure that can withstand normal cooking conditions and temperatures. Starting from the gelatinization process in excess water, the starch granules swell and gradually lose their molecular order; the amylose solubilizes and a starch gel or paste is formed. Amylose and amylopectin aggregate to form crystalline double helices stabilized by hydrogen bonds in the process known as retrogradation, forming three-dimensional crystalline structures of the B-type. An A-type crystalline structure can be obtained if retrograded starch is formed in gelatinized starch stored at high temperature (e.g., 100°C) for several hours. It is now generally accepted that both A- and B-type starch structures consist of double helices. These crystallites are highly stable, showing a melting endotherm at ~120–150°C and are resistant to enzyme digestion. It is thus evident that these structures are responsible for the integrity of the noodle structure. Amylopectin molecules can also crystallize by association of the short lateral chains. Amylose retrogradation is a rather fast process, taking place in a few hours; however, amylopectin requires longer times (days or week). Amylopectin crystallites are less stable than amylose ones, with a melting point close to 55–70°C. Even though amylopectin is almost always found in greater amounts, its role in starch noodle structure is not as significant as compared to that of amylose, but its presence may have implications on noodle texture.

Retrogradation of starch leads to the formation of enzyme resistant starch (RS). In studies on gelatinized starch containing both amylose (25%) and amylopectin (75%), as in normal maize and rice starches used in starch noodles, resistant starch yield depends strongly on storage time and temperature. Resistant starch formation in gelatinized starch can also be described as the crystallization of amylose in a partially crystalline polymer system. In such a polymer system, nucleation is favored at glass transition temperatures (−5°C), while propagation is favored under conditions above the glass transition but below the melting temperature. At a high storage temperature (100°C), resistant A-type crystalline structures were formed while at lower temperatures (0–68°C), formation of B-type crystals was observed. Crystallinity of the resistant fractions increases with storage of the starch gel. This also appears to be consistent with the promotion of retrogradation in starch noodle production, in which gelatinized noodles are exposed to freezing temperatures (−5–0°C) in mung bean thread noodles or plain washing in water for conditioning and tempering in rice and maize starch noodles at room temperature (25–35°C). In studies that compared starches and flours from wheat, maize, rice, and potato for optimum RS production, the recommended process involves gelatinization in excess water, cooling to room temperature followed by overnight freezing and a low-temperature drying at 60°C. These processes are parallel to that required in most starch noodle production systems.

Formation of RS is evidently affected by the water content and temperature. A minimum of water is necessary for plasticization of the environment and for incorporation into the crystal structure. The dependence of retrogradation on starch concentration has been reported by several workers. It was reported that a bell-shaped distribution of retrogradation, ΔH, as a function of starch concentration occurred with maximum values in the range of 50–60% starch. These DSC data support X-ray diffraction studies which reported that 50% starch gels produced the most intense X-ray pattern. It is interesting to note that this is the approximate moisture and starch content range that is required in starch dough for extrusion or sheeting in starch noodle processing. Although these findings support the apparent thermal stability of starch noodles and sheets when exposed to normal cooking conditions, actual studies on the nature of starch noodle structure and properties from different substrates are very limited.

Drying

Most starch noodles are traditionally air-dried under the sun (Figure 6h) but much commercial production is now dried in mechanized driers which are part of a continuous process (Figure 5d). In China, in the production of jelly sheet noodles from potato and sweet potato, the gelatinized sheet is scraped and moved on to a fine wire screen conveyor that leads to a heating cabinet (Figure 5d), after which the sheet comes out ready for tempering followed by cutting, drying, and packing (Figures 5g and 5h).

Nutritional Benefits

There is renewed interest in starch noodles due to the nutritional benefits associated with their consumption. The definition of dietary fiber has broadened in recent years to include resistant starch. Starch noodles provide

not only an alternative to wheat-based pasta for celiac patients, but are also now considered a source of dietary fiber from retrograded starch recognized as a form of resistant starch. Other forms of enzyme-resistant starch include physically inaccessible starch, locked in the plant cell; the native granular starch found in food containing uncooked starch; chemically and thermally modified starches; and the indigestible starch fraction formed after heat-moisture treatment of starch (i.e., the retrograded starch formed when starch noodles are produced).

Retrograded starch is left undigested until fermented in the large intestines. It can be considered invisible fiber, because its consumption is not coupled with coarseness and discoloration normally associated with traditional sources of fiber such as brans and wholegrain cereals. In earlier work, retrograded amylose was considered to be non-nutritive; however, it was demonstrated that amylases gradually degrade the structure. Glucose and oligosaccharides are released from retrograded starch over an extended period through the normal digestive process. Studies have shown that extruded noodles from high amylose rice varieties significantly reduced starch digestibility (by 15%) and the glycemic index in normal individuals (by 36%). This has been attributed to starch gelatinization and retrogradation during processing. The low glycemic response from noodles implies that these foods may have health benefits to both normal and diabetic individuals through sustained energy level and prolonged satiety.

Dietary fiber (DF) is a significant food component that can minimize the risk of colon cancer, cardiovascular disease, and diabetes. Studies on test animals demonstrated that resistant starch offers advantages comparable to traditional sources of dietary fiber in providing fecal bulk and encouragement of the growth of beneficial microflora. The physiological effects of RS are comparable to those of fermentable dietary fibers. A lower acidity in the colon is attained through the fermentation of carbohydrates by gut bacteria to short-chain fatty acids (SCFAs) such as acetic, propionic, and butyric acids. SCFA production offers some defense against colon cancer by epithelial proliferation, increased absorption of minerals, and bacterial metabolism of bile salts and balance of bacterial microflora.

Food consumption patterns are affected by factors of convenience in current fast-paced lifestyles and consumer demand for healthy natural food products. This development had triggered a lot of research on resistant starch, its health implications, and methods of analysis as a dietary fiber for appropriate food labeling purposes. Starch noodles can now be presented with a new image as a nutritious energy food that can be recommended as a vehicle for the modulation of glucose release in the blood for diabetic patients and sustained energy level for athletes as well as rich source of dietary fiber. Optimization studies on resistant starch formation in starch noodles with the use of different substrates and process variables may present alternative ways by which resistant starch can be offered as a functional food ingredient in both traditional and nontraditional food products.

Asian Wheat Flour Noodles

G B Crosbie, Department of Agriculture, Merredin, WA, Australia
A S Ross, Oregon State University, Corvallis, OR, USA

Published by Elsevier Ltd.

Introduction

Asian noodles, which have relatively simple origins in China, have evolved into a vast array of varieties. These types vary with respect to formulation, process, and quality attributes of the finished products. The aim of this article is to describe the various noodle types and manufacturing processes, and the effects of processing variables and raw materials on product quality.

Classification of Noodles

Noodles are often classified on the basis of raw materials, dimensions of the strands, and by the method of manufacture. A similar approach is used here.

Classification Based on Ingredients

The main ingredients in Asian noodles are flour, salt (sodium chloride), and water, and in the case of alkaline noodles, solutions of sodium carbonate, potassium carbonate, sodium bicarbonate, or sodium hydroxide. The alkaline solutions are known as lye water or "kansui." On this basis, noodles can be classified as nonalkaline or alkaline depending on the presence or absence of alkaline salts. There has been a tendency for nonalkaline noodles to be referred to as "white salted," but this category is not exclusively white and containing sodium chloride. In Japan a creamy colored noodle is preferred, and in China this noodle type is manufactured with and without salt. Also, sodium chloride may be used in addition to alkaline salts in the manufacture of alkaline noodles. While there is also a tendency for Japanese-style white salted noodles to be referred to generally as "udon," in Japan there remains a preference for such noodles to be referred to by specific names that relate to noodle strand size – of which udon is one (see below and Table 3).

In addition, ingredients such as starches, gums, phosphate salts, and colorants are commonly used for specific effects in both nonalkaline and alkaline noodle types.

"Soba" is a popular noodle consumed in Japan, and is usually made from a mixture of buckwheat flour and high-protein wheaten flour, water, and salt. The high-protein content of the wheaten flour compensates for the lack of gluten-forming protein in buckwheat flour. Basic formulations for various noodle types are given in Table 1.

Classification Based on Manufacturing Process

A small percentage of noodles are hand-made and valued for their fine texture, including types made by stretching, cutting, or shaving of a hand-mixed dough. Most noodles are made by machine, with the basic steps of dough mixing, sheeting, combining of sheets, resting, rolling, and cutting being used in most noodle plants. Subsequent treatment varies and noodles may be manufactured in various final forms for sale, including fresh (raw), semidried, dried, boiled, steamed, steamed and dried, steamed and fried, and frozen types. These types are described in more detail later in this article.

Classification Based on Noodle Size

Noodles commonly have a rectangular cross-section but may be square or round depending upon the thickness of the noodle sheet and the shape and size of the cutting rolls used. In Japan, there is a wide range of nonalkaline types which differ markedly in their width (Table 2). Throughout Asia, an extensive range of noodle types and sizes is manufactured among both alkaline and nonalkaline noodles (Table 3).

The Noodle-Making Process and Its Effects on Noodle Quality

Basic Processing Steps

Mixing Vertical or horizontal dough mixers and a variety of mixing processes are used to blend

Table 1 Typical noodle formulations

Noodle type	Country or region	Preferred color of product for market[a]	Basic ingredients: Flour (parts)	Water[b] (parts)	NaCl (parts)	Alkali (parts)	Alkali (type)	Other key ingredients	Reference
Nonalkaline

ingredients and, depending upon the amount of water added, to develop a crumb or dough. Saline or alkaline solutions are usually incorporated with the dry ingredients at levels of ~28–35% (based on flour weight) for nonalkaline noodles and ~28–34% for alkaline noodles. Moisture additions may increase from 40% to 47% if vacuum is applied during mixing. In forming the initial dough crumb, the main focus is even hydration of the dry ingredients and there is little gluten development. Estimation of optimal water addition is generally based on an assessment of crumb size (for low water additions) and satisfactory sheeting and handling properties. The amount of water added affects almost all processing operations and final product quality. Low water addition and crumb formation is favored in the preparation of noodles that will be dried prior to distribution. Use of higher amounts of water under vacuum mixing has advantages in minimizing gluten damage during subsequent sheeting, combining, and rolling operations, increasing product yield of raw noodles, and reducing cooking time for processes involving boiling or steaming.

The maintenance of close control of dough temperature is important in the mixing stage of the noodle process, and too low or too high a temperature can have adverse effects on product quality. In experimental studies, the Japanese National Foods Research Institute specifies that room temperature should be 25°C ± 2°C and the crumb or dough temperature 26°C ± 2°C. These specifications could also be used as a guide for commercial noodle manufacture.

Initial sheeting and combining The crumb or dough is split into two and each is passed through a set of sheeting rolls. The two sheets are then combined through a single set of rolls to facilitate gluten development. At this stage, the sheet is usually rested for periods of up to 1 h, although longer rest periods are used in some plants. The rest period allows for relaxation of the gluten structure and minimizes damage to the gluten during subsequent reductions in sheet thickness. Studies at the Bread Research Institute of Australia that were reported in 1987 showed that rested Cantonese noodle doughs had a more continuous protein matrix, fewer airspaces and less

Table 2 Classification of Japanese-style white salted noodles in Japan by width

protein contraction on the sheet surfaces. The better-developed protein matrix was considered to result in improved noodle-eating quality.

Rolling of the sheet The sheet is then passed through a series of rolls to progressively reduce the sheet thickness. This stage of the process can impact substantially upon noodle-eating quality. Important factors include rate of reduction in sheet thickness, moisture content of the sheet, direction of sheeting, and the temperature of the rolls. The reduction in sheet thickness should ideally not be greater than 30% at any pass through a pair of rolls, otherwise the gluten structure may be damaged and the eating quality of the noodle impaired. The moisture content of the sheet is important with higher moisture levels protecting the gluten structure from damage. The superior texture of hand-made noodles has been associated with improved gluten development through a combination of higher dough moisture content and kneading of the dough after mixing. The kneading leads to randomized development of the gluten rather than the unidirectional development achieved through conventional sheeting. New techniques have attempted to achieve the characteristics of hand-made noodles in mechanized production. Strategies employed have included the use of corrugated or waved rolls that are reported to simulate the effects of multidirectional sheeting.

The temperature of the sheeting rolls is important, and water-jacketing of the rolls assists in controlling sheet temperature. Changes in temperature also affect sheet elasticity and viscosity. These factors, in turn, influence the roll gap settings required to achieve the desired final sheet thickness. Excessive roll temperatures can lead to surface drying of dough sheets, and the Japanese National Foods Research Institute has reported that low roll temperatures cause roughness of the noodle surface.

Cutting After reduction of the noodle sheet to its final thickness, the noodles are cut lengthways through cutting rolls. Cutting rolls are available to produce noodles that vary in width from ~1.0 mm to 7.5 mm. The final dimensions of the noodle strands are determined by the cutting rolls and the thickness by the sheeting process. These dimensions influence time taken for drying (for dried noodles) and cooking (for steamed and boiled noodles).

Processing for Specific Noodle Types

Dried noodles Drying preserves noodles and prolongs their shelf life by reducing water activity to a level that greatly restricts or stops quality deterioration and microbial growth. Various temperature, humidity, and time profiles are used commercially. A common method for drying "udon" involves temperature and humidity ranges of 35–50°C and 70–75% RH. Temperature is lowered in steps over a period of 6 h, and final moisture content is generally less than 14%. Other methods involve drying at 20–35°C for 10–20 h and at temperatures under 20°C with ambient low humidity air in the Japanese winter. The latter is traditionally used for the drying of hand-made "somen," and has the advantage of giving slightly whiter color due to reduced browning. Very high-temperature drying (> 70°C), as used for pasta, is not commonly applied. As a result of high ambient temperatures in Southeast Asia, noodles may be simply dried in the sun. Although this use of natural resources is economical, the lack of control of both temperature and humidity could lead to inconsistent quality.

Boiled noodles Several types of noodles are boiled prior to sale. These include boiled udon and the alkaline "Hokkien" noodles manufactured in Southeast Asia. After cooking, boiled udon noodles are rapidly cooled in chilled water, drained, automatically packed, and refrigerated at ~5°C. In contrast to boiled udon, Hokkien noodles are only parboiled by the manufacturer and the final cooking is done immediately before eating. Hokkien noodles are cooled either by air or chilled water, drained, sprayed with oil to minimize sticking, and are usually packed in plastic bags.

Long life noodles are boiled noodles, which can be stored at ambient temperature for long periods. In this case the noodles are formed, partly boiled, cooled, soaked in a dilute organic acid solution such as lactic acid, surface treated with oil or α-amylase to stop sticking and then packed and pasteurized at temperatures exceeding 90°C.

Boiling time required varies according to noodle size, but a typical time period for complete boiling would be 20 min for raw udon, with a moisture content of ~35% and with cross-sectional dimensions of 3.0 mm × 2.5 mm. Boiling time decreases with increased moisture content and increases with the size of the noodle strand.

The Japanese National Foods Research Institute indicates that pH of water used in boiling udon should be maintained at 5.5–6.0 to minimize boiling losses. The pH of the water is not so critical for alkaline noodles, which leach alkaline salts into the boiling water. Where pH control is required, organic acids such as lactic, malic, and citric acids are suitable.

Frozen noodles In the manufacture of frozen noodles, raw noodles are boiled, washed in chilled water, drained and rapidly frozen at $-30°C$ or below. High-quality frozen noodles are usually made by mixing under vacuum, allowing increased water addition. The additional water improves gluten hydration and development, reduces gluten damage during sheeting, and reduces boiling time by allowing more rapid heat transfer into the noodle. Rapid freezing is also beneficial as it ensures small water crystals which are less likely to disrupt the gluten network than the larger water crystals formed at slower freezing rates. Frozen noodles can have very high quality, approaching that of fresh (raw) noodles. The process is critical and poor results can occur if any of the key steps are not finely tuned.

Instant steamed and fried noodles Steamed and fried instant noodles were introduced in the late 1950s and early 1960s in Japan and Korea. They have fast rehydration rates on final cooking and this convenience makes them very popular. Their basic processing, up to cutting, is common with other noodle types. Dough moisture should be low enough to promote fast dehydration during frying. However, dough moisture must also be sufficiently high to promote full gelatinization of starch during steaming and adequate development of the gluten structure. Adequate gluten development is needed for its contribution to noodle texture and to minimize excessive softening of noodles in hot soup.

The process deviates after cutting. First the noodles are waved and formed into the appropriate shape for sale. The wave conformation assists in even penetration of steam and frying oil. Various devices ranging from hinged baffles to rubber flaps, both placed immediately after the cutting rolls are used to form the waved noodles. The devices allow the buildup and release of the noodles that cause the wave pattern to form. The noodles are then steamed, and steaming should be extensive enough to cook the noodles right through, that is, to the disappearance of the doughy core at the center of the noodle strand. This allows full swelling of the starch on rehydration, which is associated with good texture.

The frying step simultaneously cooks and dehydrates the product. In addition, frying creates voids through violent steam release, which increases the surface area of noodles and assists in speeding rehydration rates. Frying further gelatinizes the starch, the block of noodles is set into shape to facilitate easy packaging, and a desirable golden color is developed. Instant steamed and fried noodles have a relatively high fat content ($\sim$15–22%) compared with steamed and dried instant noodles (1–3%). Some manufacturers, to decrease oil uptake, take measures such as partially drying the noodles prior to frying or using edible coatings, sometimes polysaccharide-derived. Much of this work is the subject of patent coverage.

Instant steamed and dried noodles Instant steamed and dried noodles are manufactured in several forms, with the most popular being a waved form in blocks, similar to instant steamed and fried noodles.

These noodles may become increasingly popular with consumers because of their low fat content.

Raw Materials and Their Effects on Noodle Quality

Wheat

The principal consideration in selecting wheat for the milling of noodle flours is that it be well-filled, of good appearance, and not damaged by weather or grain drying. Wheat used for the manufacture of noodle flour should have an appropriate balance of protein content, protein quality (as indicated by dough properties) and starch quality for the targeted noodle type. The presence of excessive levels of α-amylase, either through preharvest sprouting or late-maturity α-amylase, can have deleterious effects during processing and on the quality of the final product – these include increased boiling losses and reduced eating quality. High levels of protease, associated with rain damage, may lead to increased breakage of noodles during drying and poor color in both alkaline and nonalkaline noodles.

In addition to having access to sound wheat of high milling quality, the milling process is also important. The highest-quality noodle flours are associated with low extraction milling and low ash levels in the flour. This can be achieved either by milling to a low extraction rate, or by milling conventionally and utilizing flour streams least contaminated by bran particles.

Flour

Typical flour specifications for the different types of noodles are given in Table 4.

Flour attributes and noodle appearance Flour extraction levels and ash contents have a profound influence on noodle appearance. Higher flour extraction levels generally lead to duller noodles with a higher propensity to darken during dough processing. Low flour extraction and ash levels are preferred for the manufacture of noodles that retain a clean, bright appearance after cooking.

Table 4 Typical specifications for noodle flours

Noodle type	*Country/region*	*Moisture (%)*	*Protein (%)*	*Wet gluten (%)*	*Ash (%)*	*Falling number (sec)*	*Reference*
Nonalkaline							
Udon	Japan		8.0–10.0		0.36–0.40		1
Dried noodles	China						2
Superfine grade		≤14.5		≥28	≤0.55	≥200	
Common grade		≤14.5		≥26	≤0.70	≥200	
Dried noodles	China		9.5–11.0				3
Alkaline							
Ramen	Japan		10.5–12.0		0.33–0.38		1
Cantonese	SE Asia		~12.0				4
Cantonese (high quality)	SE Asia		12.0–13.0				5
Cantonese	SE Asia		10.0–12.0				5
Wonton	SE Asia		>13.0				5
Hokkien	SE Asia		~10.5				4
Hokkien	SE Asia		10.0–11.5				6
Bamee	Thailand		11.5–13.0		≤0.46		7
Instant noodles (ramyon)	Korea						8
Common		13.5–14.0	10.3–10.6		0.50–0.54		
High quality		13.5–14.0	9.4–10.6		0.40–0.44		
Cup noodles		13.5–14.0	11.0–11.5		0.40–0.45		
Instant	Taiwan		11.5–13.0		0.45–0.55		9
Instant	Philippines		~10.0				9
Instant	Indonesia		11.0–12.0				9

Raw noodles discolor with time. This is associated with polyphenol oxidase (PPO), activity, flour extraction rate, weather damage, and variety. Wheat breeders in the exporting nations have been working diligently to decrease PPO levels, and hence raw noodle darkening, in all potential noodle wheat but noodle darkening is still an issue. In addition to PPO in the flour itself, PPO is preferentially localized in the bran. Higher flour extraction levels lead to higher numbers of bran particles in flour and increased visible speck counts in raw and boiled noodles. If raw noodles are held for too long before cooking, the specks become darker and more visible due to the effects of PPO. Increased flour protein content also decreases noodle brightness in a range of noodle types but has little effect on noodle darkening over time.

The yellowness of the flour, mainly due to the presence of xanthophyll pigments, has a significant effect on the color of raw and cooked noodles. In Japan, the main preference is for creamy-colored udon, associated with a moderate level of yellow pigment in the flour. In addition to the effect of yellow pigment in the flour, the yellowness of ramen and other types of alkaline noodles is also influenced by the effect of the alkali on flavonoid compounds in the flour. Flour particle size also influences noodle brightness, with decreased particle size, at equivalent starch damage levels associated with brighter noodles.

Flour and noodle texture The principal characteristics of flour that affect noodle texture are: protein content, reflecting the relative proportions of the two main components of the flour, protein and starch, and the compositions of these two components. Flour lipids may also play an important role.

Flour protein, in its hydrated form as gluten, provides the basic structure of a noodle strand. Increased protein content in the flour, and also increased gluten strength, reflecting the composition of the protein, have significant effects on various aspects of noodle processing and texture. Increased protein content has been related in the literature with increased noodle hardness. However, there is conflicting evidence in the literature regarding the relative importance of protein content and gluten composition. In studies where sample sets with small ranges of protein content have been selected, a clear effect of protein composition on noodle texture can be observed. Where the

range of protein content is greater, protein content seems to dominate the effects of gluten composition on noodle texture. In the last few years study of the effects of gluten composition on noodle texture has become a dynamic area of research and readers are advised to closely monitor the developments regarding this issue.

Starch also has a significant effect on noodle texture. Initial studies on the effect of starch on noodle texture focused on the pasting characteristics of isolated starch, and showed that high starch paste peak viscosity and correspondingly high levels of paste breakdown during shear were preferred for Japanese udon. Later studies indicated that the starch component of flour for udon should have high-swelling properties and these could be predicted from flour swelling volume (FSV) tests. The high-swelling starch type was found to be closely linked to the desired soft and elastic texture in udon.

Early studies also indicated a possible requirement for low paste breakdown in starch isolated from flour for Japanese ramen. Recent studies have indicated that flour with low-swelling starch is required to give the firmness, lack of stickiness, and other desired characteristics in ramen. However, this may not be a common requirement of all noodles made with the inclusion of alkali.

As research has progressed, it has become apparent that the swelling characteristics of flour appear to have a primary effect on boiled noodle yield and texture. Associations between paste viscosity measurements and noodle texture appear likely to reflect the common dependence of these characteristics on flour swelling.

More recently the genetic underpinnings of the main differences in starch characteristics for wheats preferred for udon have been elucidated. Wheat amylose is synthesized by three populations of the enzyme Granule Bound Starch Synthase (GBSS), which are coded for by genes on chromosomes 4A, 7A, and 7D of wheat. Each of the genes has at least two alleles, one of which is "null." Presence of one or more null alleles leads to a decreased synthesis of GBSS, decreased synthesis of amylose, and a corresponding increase in amylopectin. The increased relative proportion of the highly branched amylopectin leads to greater swelling of starch granules during gelatinization, which can be detected as increased FSV, and as the unique soft and elastic texture desired in udon and some other specialized noodle types.

Effects of Salt

High levels of salt, up to 8%, are used in some dried noodles, particularly hand-made. Salt influences the ease or rate of drying of noodles, modifies enzymatic activity, and prolongs shelf life. It also reduces boiling time, causes a softer mouth-feel and makes dough handling easier.

Effects of Alkali

Common alkalis used in the manufacture of alkaline noodles include: sodium carbonate, potassium carbonate, and sodium bicarbonate. Mixtures of the alkalis are commonly used, with 1% (flour basis) of a 40 : 60 mixture of sodium carbonate and potassium carbonate being incorporated with 1% (flour basis) of salt in the Japanese National Foods Research Institute method for ramen.

In Malaysia and Singapore, sodium hydroxide is sometimes used in the manufacture of Hokkien noodles. Here the use of this very strong alkali is favored for its positive effects on noodle brightness and yellowness, but this may be offset to some degree by a more rapid deterioration in cooked noodle texture with time.

The use of alkali has a strong influence on noodle texture due to its effects on gluten and starch properties and these differ according to the type of alkali used. Sodium hydroxide has a more substantial effect on starch gelatinization than sodium carbonate, even to the extent of inducing gelatinization of starch at room temperature. Noodles made from sodium hydroxide are reported to have a softer texture than those prepared from sodium carbonate and this is likely to be associated with increased starch swelling. A consequence of this is that the optimum starch type required for flour used in the manufacture of alkaline noodles may vary according to the type of alkali used.

Effects of Other Ingredients

Ingredients that have been used in noodle formulations include starches, gums, emulsifiers, enzymes, and colorings. For frozen noodles, nonwheat starches are frequently included in formulations. Modified starches designed to enhance freeze–thaw stability or slow retrogradation rates can improve the texture of the final cooked product through a softer but more elastic texture. In instant noodles, potato starch or other modified starches can be used to alter noodle texture and to increase the rate of rehydration on final preparation.

There are many types of gums available that currently or potentially have applications in noodles. These include; guar and locust bean gums, alginates, including propylene glycol alginate (PGA), carrageenans, xanthan, gellan, and cellulosic gums. Gums are added in low amounts (often between 0.5% and 1.5% of flour weight) and are commonly used to make

noodles firmer, increase water-holding capacity in pre-boiled noodles, increase freeze–thaw stability and reduce ice crystal formation in frozen noodles, and to reduce fat uptake in fried noodles. In choosing a gum, one needs to consider the type of gum, the viscosity of the gum, its ease of hydration, and its mesh, or particle size. Hydration and particle size are crucial factors in some noodle formulations because of the low water additions used. As a rule, gums should be fully hydrated prior to addition to the flour.

Monoglycerides and other emulsifiers can be used to modify dough sheeting and handling characteristics or to restrict starch swelling on cooking. The benefit of the latter is to reduce surface erosion and cooking losses during boiling, but this needs to be balanced against some reduction in cooked noodle yield.

More recently a range of enzymes has been developed for use in noodles. Transglutaminase, which forms glutamyl-lysine cross-links in gluten, can be used to increase break strength in uncooked dried noodles as well as produce firmer boiled noodles. Lipases that produce monoglycerides and other lipid species *in situ* have been developed commercially and are claimed to reduce surface stickiness and increase firmness and cooking tolerance of noodles in a similar fashion to the use of monoglycerides. Oxidoreductases, such as glucose oxidase, are claimed to increase noodle firmness, and to reduce cooking losses and stickiness. Surface application of amylases is also suggested for reduction of surface stickiness in packaged and precooked noodles. The patent literature and technical literature from enzyme suppliers provide rich sources of further suggestions for the use of enzyme technology in noodle applications.

Proteins, such as gluten or whey protein isolates can also be added to improve noodle firmness. Addition of egg white tends to make noodles both firmer and less elastic.

Final noodle color may also be adjusted by the addition of food colorants. β-carotene is often used as a means of adjusting udon to a creamy yellow color. In Japan, riboflavin (vitamin B_2) may be used in alkaline noodles to accentuate the yellow color of ramen. In Southeast Asia, tartrazine is a common colorant used in the manufacture of intensely yellow Hokkien noodles.

NUTRACEUTICALS FROM GRAINS

P A Franks, Food Science Australia, North Ryde, NSW, Australia

Introduction

This article deals with a class of grain components selected, not on the basis of their chemical structure, but rather by their physiological functionality. Nutraceuticals are a diverse group of chemical compounds, but they all demonstrate a beneficial impact on our bodies. Whilst it is clear that food is eaten to provide energy and the building blocks for growth, it has become increasingly popular in the "West" to consume foods for their ability to improve and protect our health. After a brief introduction to the concept of functional foods and nutraceuticals, this article presents the major classes of grain nutraceuticals and describes their potential health benefits. Although most nutraceuticals mentioned here are found in all grains, their concentrations vary widely. Where a particular grain has high levels of the nutraceutical under discussion, it is specifically mentioned.

Background

In the late 1980s, a trend in food products was emerging in which foods were recognized as contributing more than simply sustenance and nutrition. Not only was food seen as a quantitative source of protein, carbohydrates, and fats to maintain (human) viability, but it was recognized that some food components were capable of improving health and well-being and therefore capable of effecting qualitative changes in health. The resulting foods are known as functional foods, indicating that their consumption serves a biological function, such as reducing cholesterol level, improving heart health, or improving bowel health, to name but a few. The chemical components responsible for this functionality are known as nutraceuticals. The definition of nutraceuticals has evolved but generally they are food components, which provide medical or health benefits to the consumer. Where these compounds are consumed in purified form (as tablets or as potions) in addition to a normal meal, they are better described as food supplements.

The design of functional foods and the focus on nutraceuticals to improve health represents quite a paradigm shift in health treatment in the West. Western medicines have traditionally been administered to patients to treat disease, but in the East, medicine is also given to maintain health and prevent disease. The move to functional foods can be seen as a move towards the traditional Chinese medicine paradigm, where the emphasis is on prevention rather than cure. Many cultures have medicinal plants, but the Chinese and Indian (Ayurvedic) systems are particularly comprehensive. The UK *materia medica*, for example, lists some 300 plants. The Chinese *materia medica*, on the other hand, lists some 7000 plants. It is, therefore, understandable that the first country to regulate the use of such bioactives in foods was Japan, where East meets West.

The Government of Japan, in collaboration with industry, introduced Foods for Specified Health Uses (FOSHU) laws to regulate functional foods and nutraceutical claims. The system began to evolve in the late 1980s and was implemented in the early

1990s. At the time of writing, there are several hundred functional foods on the FOSHU list. The existence of this accreditation agency in Japan has resulted in a growing distinction in the marketplace, between functional and "normal" food products, based on verified functionality. It has also generated growing customer awareness. For the food manufacturer, this distinction has meant an ability to achieve the higher prices common for FOSHU-accredited products in the market place.

In Australia and the USA, nutraceuticals have traditionally encompassed primarily the vitamins, fiber, and minerals. More recently, phytostanols and phytoestrogens have been touted; so too have omega 3 fatty acids and polyphenols, but there is a strong movement away from describing functional foods in terms of their nutraceutical components and towards descriptions in terms of physiological effect.

Margarines containing hypocholesterolemic nutraceuticals are, for example, advertised not for their phytostanol content, but for their ability to lower cholesterol levels. Other functionalities of interest, at the time of writing, include cancer prevention, cardiovascular health, obesity reduction, arteriosclerosis prevention, stamina enhancement, immune function improvement, bone health, eye health, mental health, and prevention of neuro-degeneration. Nutraceuticals are also targeted by food manufacturers at particular age groups and lifestyle groups. For 14–34 year olds, for example, these include functional soft drinks, "booster"/energy drinks, confectionary, quick-fix tonics, hangover cures, and performance enhancement (sports) drinks; and for 35–60 year olds, the major driving force in the nutraceuticals market, age-related disease prevention predominates for conditions such as osteoporosis, mental health, joint health, eye health, heart health, and bowel health.

There have been a large number of individual market studies on the functional food phenomenon, but for a good review the reader is recommended to a "meta review" by Sloan. Of the ten key trends identified in the review, the major ones representing potential for grain-derived nutraceuticals are:

- condition-specific marketing (Foods targeting specific medical conditions such as diabetes, high cholesterol etc.);
- gender, age, and ethnic positioning (Foods to minimize menopausal symptoms, hormone related osteoporosis etc.);
- weight, satiety, and appetite suppression (Food with low glycemic index);
- functional snacks and natural functional ingredients (both well suited to grain products); and
- nontraditional food markets (eye health, oral health, cosmetic application of food components).

Grains have traditionally been consumed for their part in staple diets, providing quantitative sources of protein, carbohydrates and, to some extent, vitamins. The differences between the grains in these respects are not large, although the amino acid composition, carbohydrate composition, and digestibility do vary from one grain type to another. There are, however, significant differences in the minor components and their bioactivities (nutraceutical properties). The nutraceuticals from a particular grain can be delivered to the consumer by including the whole grain in the target food, by including nutraceutical-rich fractions, or by adding purified nutraceuticals.

Whereas the focus of the consumer is, thus, increasingly on the physiological functionality of a food product, the focus of the food manufacturer needs to be on the optimal combination of ingredients to deliver functionality and flavor. The focus of the ingredient supplier or grower needs to be on the nutraceutical levels of their ingredients. The following sections discuss some of the major nutraceuticals found in grains.

Storage Compounds

Grains, by their nature, are rich in storage compounds such as amylose, amylopectin, storage proteins, and vitamins (e.g., tocopherol, tocotrienols). Traditional milling and processing results, primarily, in liberation of the components of the starchy endosperm containing these storage compounds and, in wheat, this is also the major quantitative source of beta-glucans. It has been suggested, however, that the nonstarch (bran and germ) fraction, which may account for up to 25% of the grain in wheat, for example, may contain up to 95% of the important nutraceuticals and phytochemicals. Bran contains, for example, phenolic acids, lignans, flavonoids, vitamins, and phytosterols and the potential exists to render these more bioavailable by further processing.

Starch

Starch is a polysaccharide comprised primarily of amylose and amylopectin – two polymers distinguished by their degree of branching. Presentation of carbohydrates to the digestive system as amylose induces a slower breakdown in the stomach in the first instance, consequently, resulting in a slower release of sugar, and thus, a lower glycemic index than the same amount as pure sugars. The slow release of sugar reduces peak blood glucose levels and the resultant diabetic stress that this generates. The starch

polysaccharides continue to be metabolized, however, throughout the digestive system with some forms being more resistant to digestion than others. These resistant starches fall into four categories, termed RS1, 2, 3, and 4.

RS1 refers to resistance conferred due to physical entrapment of starch, as found in partly milled grains, seeds, or legumes. RS2 includes starch granules that are highly resistant to digestion by α-amylase until gelatinized. This type is found in high amylose maize starch. RS3 relates to the retrograded starch polymers from food processing of grains such as chickpea, rice, etc. RS4 includes chemically modified, commercially produced resistant starches. These are likely to be degraded by amylases to alcohol-soluble fractions and are used in many baby-foods applications.

Protein

Although, the exact composition of seed storage proteins may vary considerably from one plant variety to another, it appears that the subunit structure and physical properties are quite similar across many dicotyledonous and monocotyledonous plants. The surface properties of the 11S subunit globulins, for example, appear similar and their hydro-phobicity has been suggested to underlie their hypocholesterolemic (cholesterol-lowering) activity. Certain protein isolates have, as a result, been used as nutraceuticals based on the hypolipidemic effect associated with certain 11S globulins.

Although seed storage proteins are usually not bioactive, it should be remembered that during digestion peptides and amino acids produced may have bioactivity. Hydrophobic peptides, for example, have been found to bind to bile resulting in a reduction of blood serum cholesterol. Also, a correlation between plasma cholesterol level and the hydrophobicity of peptic pancreatic digests exists. The peptic hydrolysates of wheat gluten and rice prolamin and glutelin proteins have been shown to possess an opioid-like activity. Such peptides have been termed exorphins because of their exogenous origin and their morphine-like nature.

Recent studies have focused also on the potential of various protein concentrates for the treatment and prevention of hypertension. This has been attributed to angiotensin-converting enzyme (ACE) inhibitory peptides in the storage proteins of corn, rice, and soybean.

Fiber

Crude fiber is contained mainly in the seedcoat and relatively little is carried through processing into the starch, protein, or oil fractions, which are the major food-processing streams. The major crude fiber components are cellulose and hemicellulose and they appear in the bran fraction after milling. The term "soluble fiber" has been applied to nonstarch carbohydrate fractions which are water soluble but not digested in the stomach or small intestine. If metabolized by gut flora in the large intestine, the soluble fiber can be considered a pre-biotic. This is because it supports the growth of the organisms and the resulting production of short chain fatty acids such as butyric acid, which has been shown to be an effective inhibitor of bowel cancers. Such an effect has been demonstrated for brewers spent grain, which is derived from germinated barley. Patients with mild ulcerative colitis are reported to have responded well to this grain, fed as a prebiotic, resulting in increased stool butyrate concentrations. Crude fiber can also function simply as a fecal-bulking agent, reducing the residence time of food (and toxins) in the bowel, and increasing stool weight. Bran consumption has been demonstrated to elicit a reduction in LDL-cholesterol (bad cholesterol), but the effect is dependent on the source of the bran. Oat and rice bran are reported to be more effective than wheat bran in reducing plasma lipoprotein risk factors for cardiovascular disease.

Oil

Legumes generally contain higher levels of lipids than do cereals. Neutral lipids are comprised primarily of triglycerides, whereas polar lipids are comprised largely of phospholipid. The fatty acid compositions of the lipids vary widely between the various grains as do their absolute levels.

It is the fatty acid molecule which appears to confer a particular lipid functionality and any discussion of oils in a nutraceutical context currently revolves around fatty acid composition. Most of the legume lipids are a good source of essential fatty acids such as linoleic and linolenic acids. Oleic and linoleic acids are the major fatty acids in chickpeas, peanuts, soybeans, lentils, garden peas, and broad beans. Unsaturated fatty acids are essential for proper function of brain and eyes and are implicated in joint health and cardiovascular health.

There are two types of essential fatty acid, omega 3 and omega 6. They are both polyunsaturated, meaning that they have at least two double bonds somewhere in the fatty acid backbone. In omega 3 fatty acids, the first double bond is after the third carbon atom from the methyl end. In omega 6 fatty acids, the first double bond is after the sixth carbon atom. Unsaturated fatty acids such as omega 3 and omega

6 fatty acids tend to have lower melting points (are more fluid at room temperature) than saturated fatty acids of the same number of carbon atoms. Melting point is significant because these fatty acids become incorporated in cell membranes and the correct fluidity is essential for optimal cell performance. Fatty acid chain length and number of unsaturated bonds further affect the melting point. When ingested, the typical C_{18} omega 3 and omega 6 fatty acids found in grains are built up to form C_{22} molecules, e.g., α-linolenic acid, an omega 3, 18:3, fatty acid is converted in the body to eicosapentaenoic acid (EPA) a C_{20} molecule with 5 double bonds and then to docosahexaenoic acid (DHA), a C_{22} molecule with 6 double bonds. These so-called omega 3 long chain polyunsaturated fatty acids have been found to be essential for proper brain and eye development. Similarly the omega 6, 18:2 C_{18} molecule linoleic acid is converted to docosapentaenoic acid, containing 5 double bonds.

As excessive amounts of omega 6 fatty acids may be detrimental to health, and omega 3 fatty acids diminish this effect, the ratio of omega 3 : omega 6 fatty acids is important for optimal health. There is some disagreement as to the best ratio, with suggestions ranging from 1 : 1 to 1 : 6. Most vegetable oils such as corn and safflower oil contain some omega 6, but very little omega 3 fatty acids. Flax seed oil is an exception with up to 58% of its fatty acids being omega 3.

Dietary deficiency of omega 3 fatty acids is reported to correlate with depression, schizophrenia, and Alzheimer's disease. Although it is not clear whether this is cause or effect, dietary supplementation of DHA has been reported to give positive results. It is also reported to reduce the inflammatory responses of arthritis and to improve the function of insulin receptors. Flaxseed oil, with its high omega 3 fatty acid content is reported to reduce high blood pressure, cholesterol level, and the risk of heart disease. It is also claimed to help treat eczema, psoriasis, arthritis, and menstrual pain. Unfortunately, the very structure which results in this bioactivity also renders the oil prone to oxidation and rancidity.

Vegetable seed oils can be rich in fat-soluble vitamins such as vitamin E (alpha tocopherol) and tocotrienols. Tocotrienols (high in rice bran oil) are claimed to reduce fat deposits in artery walls, blood cholesterol level, and growth of breast cancer cells. They are also said to provide protection from UV radiation and ozone-induced oxidative skin damage and to reduce blood clotting.

Phytosterols and Phytostanols

Phytosterols are desmethyl sterols, which share a common ring structure with cholesterol. Just as cholesterol plays a critical role in membrane structure and performance in humans, the phytosterols are essential to the membrane structure and function of plant cells. This similarity in structure is reflected in the ability of phytosterols to significantly alter the rate of uptake of both dietary and endogenously produced cholesterol from the gut, resulting in a reduction of blood serum cholesterol levels. The precise mechanism has not been determined. One theory is that phytosterols reduce cholesterol solubility and hence availability by formation of phytosterol/cholesterol complexes. It is also argued that phytosterols and cholesterol compete with each other for micellar uptake by endothelial cells.

Phytostanols are almost identical to phytosterols in structure, but are fully saturated, whereas phytosterols have one double bond in their ring structure. This chemical difference has a significant impact on their functionality. Phytostanol esters are reported to result in lower blood levels of both phytostanols and phytosterols than is the case when phytosterol esters are consumed.

Most of the phytosterols and phytostanols in corn fiber are reported to be contributed by the aleurone layer, which is reported to contain 8 times more phytosterols than the pericarp. The native phytosterols and phytostanols are not very soluble and are processed by the manufacturer to produce fatty acyl ester derivatives, which improve both solubility and ease of formulation into foods. The esters are believed to be hydrolyzed in the small intestine. There is some conflicting data, but the phytosterol esters and phytostanol esters appear to be equally efficacious in reducing blood serum LDL cholesterol levels by up to 14%. Neither ester has any significant effect on HDL levels. It has been estimated that daily consumption of phytosterols or phytostanols can reduce the risk of heart disease by up to 40%, depending on age and other factors. Both sterol and stanol esters have, however, been found to reduce the absorption of alpha and beta carotene and of vitamin E and it has been suggested that a maximum daily dietary intake be set to avoid adversely affecting carotenoid concentrations in the blood.

The major source of phytosterols is vegetable oil. Phytostanol esters are often derived from hydrogenation and subsequent esterification of a phytosterol-rich by-product fraction from pine tree pulping. Phytostanols do, however, also occur naturally in plants, and corn fiber oil has been shown to be one of the richest sources of stanols and stanol esters. The esters are of either fatty acids or phenolic acids, such as ferulic acid. In addition to the enhanced bioavailability of phytostanols and phytosterols engendered by esterification, further improvement in

bioavailability can be effected by coupling with proteins and lecithin, possibly due to an emulsification or solubilization mechanism.

Flavonoids

Flavonoids are a range of C_{15} aromatic compounds. The term flavonoids was first used for the family of yellow colored compounds with a flavone moiety, but was later extended to include various polyphenols including less intensely colored flavanones, flavon-3-ols (catechins without a C_4 carbonyl group), and red and blue anthocyanidins. Some flavonoids appear to function as plant defence systems. Catechins, for example, are astringent and have parasite deterrent properties, while isoflavones are important phytoalexins (natural plant defence chemicals) and other polyphenols function in the plant to protect it from harmful UV solar radiation. In the plant, flavonoids are generally glycosylated, while the free (unglycosylated flavonoid) aglycones are less common. The glycosides may further be acylated and both of these modifications can adversely impact on the bioavailability of the bioactive aglycone. The antioxidant potential of flavonoids is dependent on the number and arrangement of the hydroxyl groups across the structure and the presence of electron-donating and electron-withdrawing substituents. In a systematic study conducted by Miller *et al.* of the net antioxidant activity of various foods, it was shown that whole grains have almost equivalent antioxidant activity to fruits and vegetables when compared on a "per serving" basis.

Isoflavones

Isoflavonoids are found primarily in leguminous plants. They are derived from flavanones, which are found in all plants. The major dietary sources of isoflavones for humans are soybean, chickpea, and lupin seed products. A number of the isoflavones have estrogen-mimetic effects and are thus known as phytoestrogens. Epidemiological studies have demonstrated a link between consumption of soy isoflavones and reduced risk of breast cancer and prostate cancer. Isoflavones have also been shown to be active in the chemo-prevention of osteoporosis and cardiovascular disease.

Recent studies on the pharmacokinetics of isoflavone glycosides again demonstrate the important effect of digestion and gut microbial metabolism on their efficacy. Two of the commonly studied phytoestrogenic isoflavones are genistein (found in high levels in lupin and soybean) and daidzein. In their glycosylated forms, they are known as genistin and daidzin. The glycosides are more actively absorbed in the small intestine than are the aglycones, but it is only the aglycone that has estrogenic activity. The absorbed glycosides are broken down continuously by the liver without yielding active phytogestrogen. Gut flora can cleave the glycoside by means of a glucosidase enzyme, increasing the concentration of the bioactive aglycone. The net yield of the bioactive moiety from a given meal depends on a kinetic balance between these processes. In some traditional fermented soy products, such as "miso" and "tempeh" the deglycosylation has already occurred and the bioactive phytoestrogen aglycones are present at higher levels than in unprocessed soybeans.

Lignans

Lignans are another class of phytoestrogens. They possess a 2,3-dibenzylbutane structure and exist as minor constituents of many plants where they form the building blocks for the formation of lignin, which is found in the plant cell wall. Lignans from plants are believed to be precursors of the primary animal lignans enterolactone and enterodiol, being converted into these forms by intestinal bacteria. Flaxseed is one of the most abundant plant sources of lignans, with the lignan Secoisolariciresinol diglycoside (SDG) comprising the major fraction. Enterolactone and enterodiol appear to promote homeostasis, or balance, of female estrogen levels. In postmenopausal women, the effect is estrogenic whereas in premenopausal women the effect is antiestrogenic. A Finnish study found that women with high enterolactone levels in their blood had a lower risk of breast cancer and animal studies have shown reduced breast cancer and colon cancer with lignan in the feed. In males, lignans appear to interfere with the conversion of testosterone to dihydrotestosterone (DHT). DHT is required for normal growth of healthy prostate cells, but an excess amount is believed to lead to benign prostatic hyperplasia (swollen prostate). Lignan intake in the diet is reflected in the lignan concentration in the urine and higher levels are found in the prostate fluid of men with a lower risk of prostate cancer than those at increased risk.

Anthocyanins

Anthocyanins are generally highly colored pigments associated with flowers and attraction of pollinating insects. They are, however, flavonoids and can be found throughout a plant. They have been reported to be in relatively high concentrations in sunflower hulls and although the pigment quality is not generally sufficient for food-coloring applications, they would retain some bioactivity. In other plants, such as

specially bred purple sweet potatoes in Japan, certain anthocyanins have been shown to have antimutagenic activity, hepatoprotective activity, and antioxidant activity. The color of purple maize and red wheat is derived from the anthocyanin content.

Catechins

Catechins are a class of flavonols. They are C_{15} compounds and their derivatives are composed of two phenolic nuclei connected by 3 carbon units. The phenolic rings are generally di- or tri-hydroxylated and the molecule as a whole is highly reactive, with properties of metal chelation, oxidative radical scavenging, and inhibition of nitrosation. Tea catechins have also been shown to have anticariogenic activity, by means of their antibacterial activity, which inhibits plaque formation.

Nonstarch Polysaccharides

Glucans

Beta-glucan is a water-soluble, viscous, linear, high-molecular-weight polysaccharide. A Canadian study reported in 1994 found that a purified oat gum containing 80% beta-glucan, when fed to hypercholesterolemic subjects over a 4 week period, reduced LDL and total cholesterol levels by 10% and 9.2% respectively. A reduction of the LDL cholesterol level, whilst leaving the HDL cholesterol level constant, significantly reduces the risk of heart disease. Many studies on rolled oats have shown similar results.

Barley is also a source of β-glucans and besides its effect on serum cholesterol has been studied with respect to prebiotic activities. β-Glucan supports butyrate production in the colon, which has been demonstrated to inhibit various stages of growth of cancer cells.

Saponins

Saponins are glycosides with both hydrophilic and hydrophobic regions. In solution, they spontaneously form micelles. In the presence of bile, the hydrophobic portions intertwine with the bile and large micelles are formed which are too large to be absorbed across the gut wall. Saponins also interact directly with cholesterol, producing an insoluble complex that prevents cholesterol absorption from the intestine. However, saponins can also have negative bioactivity of their own, depending on their source and structure. They are a source of many of the bioactives in traditional herbal medicine and some have been shown to bind iron and reduce iron uptake. As is the case with any bioactive (and therefore potentially nutraceutical) compound, caution is necessary in incorporating saponin-rich fractions in foods.

Conclusions

Grains are a staple food in the Western diet and their contribution to nutrition is well established. The growing consumer demand for functional foods provides the opportunity to "mine" the grain components, many of which, such as bran, are discarded in low-value waste streams, for use as nutraceutical ingredients. Technologies need to be developed for cost-effective separation and purification of these potential nutraceutical compounds and systematic studies of the bio-functionalities of such purified fractions are necessary to underpin health claims. Clinical trials are essential to demonstrate purported nutraceutical activity, but are notoriously variable and often generate conflicting results. Caution must be applied to the interpretation and extrapolation of the findings of individual studies. Given the massive production of grains and the growing number of success stories, the prospects for a grain-based nutraceutical industry are encouraging.

Beriberi, A Deficiency Related to Grains

K J Carpenter, University of California, Berkeley, CA, USA

Introduction

Grains have been the major source of both energy and protein for the world's population for millenia. However, it is now realized that, when the diet lacks a variety of other foods, the grains are also needed to supply a considerable number of other essential micronutrients if those eating them are to remain healthy. But the processing of grains to remove the bran and germ, in addition to its favorable effects of increasing shelf life by removing much of the oils that can become rancid, and providing foods with a smoother feel by removing most of the fiber, does also cause the loss of a large proportion of their other nutrients.

It now appears that the emergence of the disease pellagra amongst communities in the southern states of the USA from around 1910 is explained by the introduction of machinery that allowed the replacement of stone-ground "whole corn meal" with "de-germed meal," and that this, combined with white wheaten flour and little in the way of lean meat, eggs, and milk, resulted in a diet deficient in the vitamin niacin. Until this came to be understood in the 1930s, several thousand people died and even more suffered a miserable and humiliating disease.

The following article summarizes the way in which another disease, beriberi, that was causing huge suffering in the Far East, particularly in the earlier period 1870–1910, came to be understood as the consequence in most cases of people having polished white rice as their staple food with little in the way of supplementary foods. It was the work of the pioneers struggling to understand this disease that

led to the discovery of the class of micronutrients that now is known as vitamins.

It is a complicated story with many false leads, but it provides a valuable lesson in how science does eventually advance, and the dangers of over-simplification of the problems of the real world. It also shows how it finally proved possible, as a result of collaboration between industry and academia, to "enrich" highly milled grain products so that they still provided a good contribution of vitamins and minerals.

Occurrence in Asia

The first Western physicians allowed to work in Japan in the 1870s were surprised to discover the existence of a serious disease previously unknown to them and "second only to smallpox in its ravages." In Japan, it was known as "kakké," but was soon recognized as being identical to the disease known in South-east Asia as "beriberi," a native name now universally adopted, which may originally have meant "great weakness." Characteristically, it began with a feeling of weakness in the legs and a loss of feeling in the feet. Then, in many but not all cases, the legs and then the trunk would swell with retained water. Finally, the heart would be affected so that the subject gasped for breath, and would die from heart failure.

Older records from both Japan and China showed that it had been known for some centuries, although it had been the opinion of two eighteenth century Japanese physicians that the disease had become worse after ~1750. The early records also indicated that it was largely a disease of the wet summer months and could attack even the well-off.

Infection or Malnutrition?

Those most at risk were men in the newly modernized Japanese army and navy, and also prisoners. As these were all people living together in large groups, and with the excitement in this period at other diseases being traced to the transmission of pathogenic bacteria, this seemed a likely cause for beriberi also. Yet, it was difficult, on this basis, to explain the frequent observation that a naval ship would leave its base with all its crew in good health, yet, after a month or more in isolation at sea, the disease would sweep through the crew.

Kanehiro Takaki, a surgeon on the naval staff, was directed in 1878 to work on the problem. He knew that the ships had been built in Britain and that they followed the general practices of the British navy where there was no beriberi. The only difference that caught his attention was in the rations issued to the men: the Japanese issues contained less protein and did not meet the high standard in force at that time in Europe. He therefore persuaded his superiors to permit a trial of modified rations with a proportion of the rice being replaced by meat, condensed milk, vegetables, and barley. The change was a complete success, and it was found that even just the use of barley in place of one half of the rice staple was enough to prevent the disease, which Takaki now believed to have resulted from a deficiency of protein in the earlier rations.

The Japanese army, perhaps as the result of inter-service rivalry, did not follow the navy and in the short Russo-Japanese war of 1904–05, some 100 000 of their soldiers had to be invalided home from Manchuria suffering from beriberi.

A Disease in Chickens

Meanwhile, the disease had become an equally serious problem in the Dutch East Indies (now Indonesia) (Figure 1). After a punitive military expedition had to be withdrawn because of a beriberi epidemic, the Dutch government dispatched a small commission to try to identify the bacteria responsible for the disease. After a few months, it was thought that the microorganism had been found, and Christiaan Eijkman, a young Army physician, remained behind to confirm its activity in animal models.

Some of the chickens that Eijkman had injected with blood from beriberi patients developed signs of leg weakness, but so did some of his uninjected controls, suggesting that the condition was so infectious that it could "jump" from cage to cage. Autopsies of the affected birds showed degenerated peripheral nerves. But in the following months, none of the next batch of birds developed the condition. Eijkman discovered that when the leg weakness had appeared, the man in charge of the birds had been feeding them on cooked white rice left over from feeding the beriberi victims in the adjoining hospital, instead of buying rough, feed-grade rice.

A long series of feeding trials confirmed that birds fed on white rice would become sick with leg weakness, whereas those given supplements of rice polishings (still present in feed-grade rice) remained healthy. This was only an animal disease, but a survey by the medical inspector of prisons in Java showed that prisoners who had been receiving white rice as their staple issue were susceptible to beriberi, whereas those receiving brown rice were not.

The Concept of a Vitamin

Eijkman, who believed that the disease was a kind of starch poisoning, now had to be invalided home with malaria. His successor, Gerrit Grijns, found that birds

Figure 1 Two prisoners in Java with beriberi and needing assistance to walk. (Reproduced with permission from Vorderman (1897) *Onderzoek naar het gevangenissen op Java en Madoera en het voorkomer van beri-beri order de geintemeerden*. Batavia: Jav. Boekh & Drukkerij.)

became sick even when fed on meat that had been autoclaved. After further work, his statement in 1901 was perhaps the progenitor of the "vitamin era" in nutritional research: "there occur in various natural foods substances which cannot be absent without serious injury . . . they are easily disintegrated . . . and cannot be replaced by simple chemical compounds."

The work of Eijkman and Grijns was confirmed by British investigators in Malaysia and by Americans in the Philippines, and attempts began to extract the active material from rice polishings and to concentrate it. There are moving accounts of scientists in Manila being implored by local doctors to bring a few spoonfuls of extracted syrup to save the lives of infants with beriberi, and of the babies' spectacular recoveries. Women themselves seemed less susceptible to beriberi than men, but when mothers were receiving a diet of low thiamin content, their breast-fed babies were at a high risk of dying with acute infantile beriberi.

Isolation of Thiamin

Isolation of the active factor proved very difficult. Each stage of extraction, and then further partitioning by reprecipitation involved biological assays with birds. Eventually, the next generation of Dutch workers in Indonesia was successful, obtaining a few milligrams of active crystalline material after starting with one-third of a ton of rice polishings and going through at least 16 separation stages in which much of the vitamin was lost. It was found that adding just 2 ppm of the crystals to white rice was enough to keep birds healthy. In 1931, the crystals were found to contain sulfur as well as carbon, hydrogen, nitrogen, and oxygen, and the chloride salt was shown to have the empirical formula $C_{12}H_{18}N_4SO_2Cl_2$.

There were, of course, almost innumerable ways in which these atoms could be combined. By good fortune, Robert R. Williams in the USA found that adding sodium sulfite to a solution of the vitamin led to its division into two roughly equal halves. Further work at a number of centers showed that one of these compounds contained a pyrimidine and the other a sulfathiazole ring. By 1937, a synthesis of the active molecule was achieved. It was named "thiamin or thiamine" (i.e., the sulfur-containing vitamin) and soon began to be produced and marketed as a pharmaceutical.

The Analysis of Foods

Thiamin can be oxidized to a highly fluorescent derivative, "thiochrome." This property is used to measure the thiamin contents of different foods, even at levels of less than 1 ppm. The procedure is specific, and no

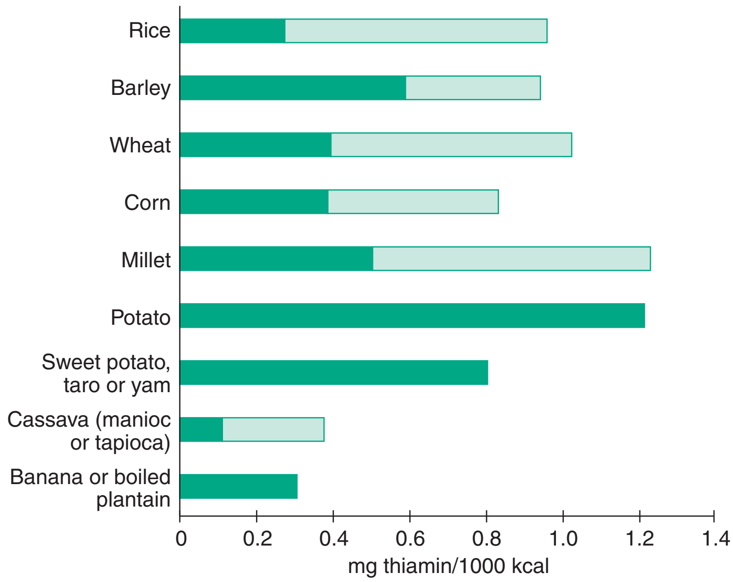

Figure 2 Representative analytical values for the thiamin content of different staple foods: (1) after husking only (■ □) and (2) after full processing (■), as explained in the text, and also for some staple root crops, etc. Sago meal is not shown, as it contains only an insignificant level of thiamin. (Reproduced with permission from Carpenter KJ (2000) *Beriberi, White Rice and Vitamin B*. Berkeley, CA: University of California Press.)

other naturally occurring compounds have been found that give the thiochrome reaction. However, thiamin can react with polyphenols and a compound present in garlic to give derivatives that are still biologically active (as will be referred to again) but do not give the thiochrome reaction. The analytical procedure may therefore underestimate the efficacy of a product. It is essential, therefore, to have a confirmatory bioassay before knowing for certain that any kind of processing has caused significant loss of thiamin.

Rice and Other Staples

Figure 2 illustrates the thiamin levels in the world's major staple foods, both when fully milled and when minimally processed. In the case of grains, the latter means removal of the husk (or hull) but no more. It is clear that, for each grain, the full milling that removes both the bran and germ results in the loss of a major portion of the thiamin originally present.

White rice is not that much lower than white wheat flour in its content of the vitamin, but after the grains have been prepared for consumption, the difference is increased. White rice is normally washed several times, and this alone can remove half the thiamin present, and boiling in excess water can again halve the level of remaining vitamin. In contrast, white wheat flour is most commonly baked into bread with yeast as the raising agent, and this causes little loss of thiamin.

There is no evidence that cooked white rice has any positively harmful qualities, but if it is the major item in a diet that contains only small amounts of foods that are richer in thiamin, so that the diet as a whole provides no more than about 0.25 mg per 1000 kcal, it is not surprising that beriberi should gradually develop.

The data in Figure 2 also explain the Japanese experience that serious problems with beriberi in their navy in the late 1800s disappeared when one-half of their rice ration was replaced by barley.

The same figure also shows the low thiamin content of tapioca prepared from cassava roots. This explains the existence of beriberi in Brazil at the same period among even well-off people whose favorite foods were tapioca and molasses. Their preferred protein supplement was dried, salted cod, which had to be soaked for several days to leach out most of the salt, which also removed most of the vitamin.

The very first reports of beriberi to reach Europe came from Portuguese priests working in the Molucca Islands (at the Eastern end of Indonesia) in the 1500s. Their staple was the locally produced sago meal, now realized to be almost pure starch, and the priests correctly attributed their weakness to a lack of "something" in this food and asked to be provided by their superiors with wheat flour.

Beriberi was also a serious problem in early spring in isolated communities in Newfoundland in the early years of the twentieth century. Their families, who would be cut off for the winter, had to buy 6 months of supplies, with white flour as their staple. They were also apparently not familiar with using yeast to leaven

bread, but cooked their flour with baking soda, and it is known that much of the thiamin present would be destroyed under the alkaline conditions during this procedure.

The Improvement of Rice

Once the association of beriberi with white rice in Asia had been established, attempts were made to replace it in some way with other foods. As already mentioned, barley was an economic and well-accepted alternative in the diet of the Japanese armed forces.

In the Philippines, a proposal was made to enforce the use of brown rice by the local military. This, of course, is rice from which the husk has been removed but not the entire bran layer and germ (embryo and scutellum) (Figure 3). This was the traditional staple of villagers in South-east Asia who had no access to mechanical rice mills. They would pound their paddy (i.e., rice still in the husk) in some kind of bowl and then winnow the product so that the lighter husks blew away, and the grains fell in a pile.

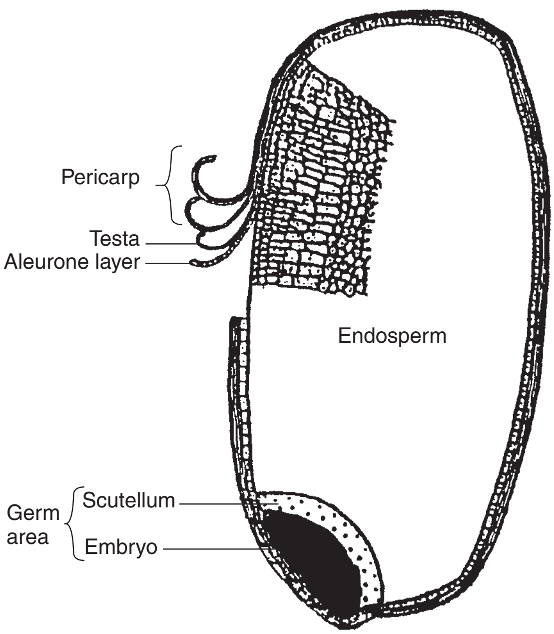

Figure 3 Dissection of a dehusked rice grain. (Reproduced with permission from Carpenter KJ (2000) *Beriberi, White Rice and Vitamin B*. Berkeley, CA: University of California Press.)

This procedure was time-consuming but created no problems when only enough was pounded for immediate use in the next 24 h. However, it was repeatedly found that in the tropics, brown rice on storage would become infested with insects of different kinds, and the oil in the bruised germ would become rancid. Since large organizations, or an army on the move, needed large-scale supplies ready for cooking, brown rice did not provide a practicable staple.

The early workers who discovered the association of beriberi with white rice had assumed that the important micronutrient was concentrated in the bran of the grain. However, it was later realized that more was present in the germ area (Table 1). Japanese millers then attempted to modify their machinery so as to remove the bran without removing the germ from the grain. The so-called "germ rice" that they were able to produce proved to be both palatable and an improved source of thiamin. However, millers were only able to produce it with certain varieties of rice, and not with the bulk of the rice favored in Japan.

A traditional method of processing rice common in Bengal is called parboiling. It had been found that if rice in the husk were to be steeped for a period in hot water and then allowed to dry in the sun, the husks cracked off more easily on pounding, and there was less breakage of the grains. Broken grains had a lower commercial value.

In Malaysia, where many immigrant groups were employed as laborers but living on their habitual diets, it was realized in ~1910 that Bengalis were remarkably free from beriberi, and studies in a mental hospital showed that replacing ordinary white rice with polished rice prepared from parboiled grains relieved

Table 1 Thiamin contributed by the different parts of a sample of dehusked rice grains

Dissected parts of rice grain	*Proportion by weight (%)*	*Thiamin*	
		Concentration in fraction (mg per 100 g)	*Contribution to 100 g grain (mg)*
Pericarp + testa + aleurone layers	6	3.1	0.186
Germ area			
Embryo	1	5.9	0.059] 0.248
Scutellum	1	18.9	0.189]
Endosperm	92	0.05	0.046
Total	100	—	0.480

Reproduced with permission from Carpenter KJ (2000) *Beriberi, White Rice and Vitamin B*. Berkeley, CA: University of California Press.

the inmates from the disease. After thiamin had been identified, analyses showed that the initial soaking of the grain caused thiamin to diffuse into the endosperm and to remain there as the grains dried out.

Again, this does not appear to be something that could be applied more widely. The traditional soaking and sun-drying leaves the rice with a characteristic musty flavor and slight discoloration, which is acceptable only to people who have grown up with it. The process can be modernized, with controlled autoclaving and vacuum-drying for so-called "conversion" of the rice, but this makes it too expensive for mass consumption in developing countries.

The final procedure for the production of "enriched" rice is to fortify it with the synthetic vitamin. For a flour, such as white wheat flour, this is relatively simple, requiring only very careful mixing of the traces of vitamin with a small quantity of flour, then the blending of the premix to larger batches. This is familiar, and indeed compulsory practice, in the USA and UK, together with other vitamins and trace minerals. As a powder, thiamin cannot be blended with grains of white rice. However, methods have been developed of preparing vitamin-rich granules with the size and appearance of rice grains, and blending these in the ratio of one granule to 200 grains, so that the mix has at least the thiamin content of brown rice. To reduce loss of the vitamin during washing and cooking, the granules are coated with a nontoxic resin at the final stage of their production. This method of enrichment has been tested in an area of the Philippines where beriberi was endemic and has proved successful in greatly reducing its incidence. Unfortunately, where widely separated villages each had a small electric mill, there were practical problems in persuading millers to pay for the premix when the product appeared unchanged, but the price had to be a little higher.

Supplementing Foods

Unfortunately, there is no convenient food that is extremely rich in thiamin. Dried brewers yeast contains 15 mg per 100 g, but many people cannot tolerate it in more than extremely small regular doses. Of the meats, pork is richest with lean pork containing 1 mg per 100 g. Beef has only about one-tenth as much. Dry peas and beans contain about 0.5 mg per 100 g. Potatoes are another useful supplement – on a dry matter basis, they have slightly more thiamin than brown rice.

In practice, reaching a desirable intake of thiamin comes usually from eating a wide variety of foods. Nineteenth-century Japanese believed that consumptions of most foods other than rice during the summer months caused "heat." Hence, food consumption was almost entirely restricted to rice consequently leading to an increase in beriberi during these months.

Is there an Antithiamin Problem?

There are many references in the literature to at least a suspicion that certain foods and beverages may be responsible for beriberi appearing in people whose intake of thiamin would otherwise be adequate.

Thiaminases

Many species of fish contain enzymes in their viscera that split thiamin molecules at the junction between its two ring structures. This was discovered when foxes, being reared for their fur and fed on a mix containing a large proportion of whole raw fish, developed a form of paralysis that responded to injections with thiamin. A similar condition was seen later in cats that had been fed on a canned food containing a large proportion of whole fish. It was believed that the thiamin in the mix had been largely destroyed after the mix had been prepared and was waiting to be autoclaved.

These experiences led to investigations as to whether humans could be similarly at risk, but it appears not. The enzymes are not present in fish muscles (i.e., fillets), and even where small fish are eaten whole, they are not ground up with other items of diet before being cooked. Lastly, it was found in animal studies that a subsequent meal with different constituents was not affected by thiaminases being present in an earlier meal.

Another source of thiaminases was found to be bracken, and their presence explained the condition known as "staggers" that occurs in horses that have been feeding on bracken. Cooked bracken, in which the thiaminase was inactivated, proved harmless to horses. The only known case of thiaminase poisoning in humans occurred in a group exploring the interior of Australia in the 1860s. Running out of provisions on their return journey, they lived on the sporocarps in the fronds of a particular fern that is now known to contain a high level of a particularly heat-resistant thiaminase. All four men developed leg weakness and lassitude; three died, and the survivor remained lame even after his safe return.

Heat-Stable Antithiamins?

It has been found that when the thiamin in a food comes into contact with polyphenols such as caffeic acid, it no longer gives a fluorescent product in the usual thiochrome procedure for the estimation of thiamin. This led some workers to suppose that drinking large quantities of tea or coffee, or chewing betel nut – all sources of polyphenols – might induce

a condition of thiamin deficiency. However, biological assays have indicated that the vitamin is still fully available.

When thiamin is incubated with garlic extracts, it undergoes a reaction with the allicin present in which the thiazole ring opens, and the sulfur atom in the ring links to the alkyl sulfide to form a disulfide compound. This is not measured in the thiochrome reaction, but in the body it is reduced to re-form the active vitamin. In fact, compounds of this type can be absorbed more efficiently by alcohol-damaged intestinal walls than ordinary thiamin. Thiamin tetra-hydrofurfuryl disulfide in particular is approved for this purpose in some countries.

Although there is no confirmed evidence of naturally occurring heat-stable compounds that inactivate thiamin, chemists have synthesized such materials. One, named "oxythiamin," has the amino group attached to the pyrimidine group in thiamin replaced by a hydroxy group. Giving it to animals results in the more rapid production of some of the signs of thiamin deficiency, although it differs from thiamin in being unable to pass the blood–brain barrier.

Acute Deficiency in the West

With the discovery that autoclaving yeast powder would destroy the thiamin, whereas the other B-vitamins were retained, it was possible to place volunteers on an artificial diet essentially free of thiamin. To the surprise of investigators, some subjects had lost appetite within 2 weeks and became nauseated and dizzy, with other mental symptoms, by 6 weeks, but with no sign of peripheral nerve damage or cardiac abnormality, which are characteristic of classic beriberi.

Trials using pigeons and rats with very deficient diets also produced appetite loss and death before any sign of leg weakness had developed. It appeared that in both humans and animals, acute deficiency of thiamin resulted in damage to the central nervous system. With slightly higher intakes, the CNS had priority, whereas peripheral nerves gradually degenerated.

Deficiencies in Total Parenteral Nutrition

There are many reports of people recovering from surgery of the gastrointestinal tract who have developed acute thiamin deficiency. They had been fed intravenously with a solution providing energy, amino acids, and minerals, but no vitamins. This is adequate for a short period, but thiamin is the first vitamin to become depleted.

In a number of cases where this type of parenteral feeding has continued for some weeks, a condition called "Wernicke's encephalopathy" has developed. Patients are confused and have characteristic involuntary eye movements. Where patients have died, autopsies have shown brain lesions analogous to those found in acutely deficient animals. The same outcome has been seen in subjects voluntarily fasting for long periods or being unable to take food because of persistent vomiting in pregnancy.

Alcoholism

One material that can be responsible for the production of thiamin deficiency is ethanol (i.e., "alcohol" in everyday speech). In developed countries where nearly everyone can afford a well-balanced diet, most of those diagnosed as being thiamin-deficient are "alcoholics." The continued ingestion of high levels of alcoholic beverages has many undesirable effects. In the present context, two are relevant. First, the alcoholic typically no longer bothers to eat a normal range of foods, partly because the beverages provide a large portion of their calorie needs and partly from nothing but their next drink being of immediate interest. Second, the high level of alcohol ingestion damages the intestinal wall so that thiamin is absorbed less efficiently, and the requirement for the vitamin increases.

Unfortunately, a small proportion of such victims develop Wernicke's encephalopathy, which may lead in turn to Korsakoff's psychosis. Such people, sometimes referred to as suffering from the Wernicke–Korsakoff syndrome, are at present incurable and have to be maintained in a mental hospital for the rest of their life. The cost of this to the state is such that some specialists have argued that it would actually be cheaper to have all beer and wine fortified with thiamin as a preventive.

There may be a genetic factor making some Western people susceptible to the cerebral form of beriberi and the Wernicke–Korsakoff syndrome, since it was seen even in Western prisoners of the Japanese in the Second World War who had white rice but no alcohol, but apparently has not been seen in Asian subjects.

Guidelines for Grain-Based Foods

C Wrigley, Food Science Australia and Wheat CRC, North Ryde, NSW, Australia
E Asp, University of Minnesota, South Anoka, MN, USA

Introduction

Nutritional guidelines have been developed for many countries to recommend those foods that should be consumed as major or minor parts of the diet. Food guide diagrams derived from the guidelines visually represent these recommendations. A common factor in these various guidelines is the recommendation that grain-based foods, should form the greatest part of the diet, preferably as whole-grain products (Whole-Grain versus Refined Products). According to the food and nutrient composition table in **Appendix**: Grain Composition Tables, grains and grain-based foods, on the per serving basis, contribute many nutrients and other food components to make food intakes nutritionally adequate. Comparisons of the mineral and vitamin contents of various grains and grain-based foods on the per serving basis from **Appendix**: Grain Composition Tables are made and discussed in **Nutrition**: Mineral Composition; Vitamin Composition. By emphasizing use of grains in the diet, nutritional guidelines provide a major boost for the grain-growing and grain-processing industries of the world.

The Many Pictorial Formats

Several food guide diagrams are pyramids (see *Dietetic Journal* and the Oldways Website) which represent the USA dietary guidelines. A pyramid diagram shows that foods at its base should be consumed in a correspondingly larger proportion of the diet than those near the apex. Pyramid formats used by the Philippines and Puerto Rico, a set of four "healthy eating pyramids," were developed by the private USA-based Oldways Preservation & Exchange Trust, the Harvard School of Public Health, and other organizations. The pyramid format was also adapted to suit the national architecture of China and Korea.

Food guide diagrams in a round format designed for other countries include circle, wheel, plate, or pie diagrams in which the sizes of the sectors or slices represent the relative importance of each food group. This format is used by Australia, Great Britain, Germany, Mexico, Portugal, and Sweden. Yet another format, a half rainbow diagram, is used by Canada. Other countries also use the USA pyramid whereas countries such as Japan provide no official illustrations of this type.

Common and Diverse Features of Dietary Guideline Diagrams

The dietary guidelines diagrammed in these figures endorse the general recommendation of the increased consumption of plant products (grains, vegetables, and fruits), balanced by a moderate intake of animal products (meat and dairy foods), combined with

restricted amounts of "treat" foods, rich in fats and sugars. The pyramid message places plant foods, especially whole-grain foods, at the base of the pyramid or as the largest slice of the pie/plate diagram. Animal-based foods are placed nearer the apex of the pyramid, or as smaller slices, with treats near the apex or in the smallest slice. Grain legumes (pulses) and nuts are generally placed at an intermediate position together with fruits.

These guideline recommendations are broadly based on international research findings about the balance of food sources that are conducive to the maintenance of good health. Variations from one country to another reflect the differing traditional food types characteristic of each culture. For example, the foods illustrated in the diet pagoda of China include prominent representations of white steamed breads, plus rice and a cob of corn, whereas western-style foods are represented in the US, Canadian, and British illustrations (see *Dietetic Journal* and the Oldways Website).

The four Oldways pyramids emphasize regional diversity of traditional foods for the Mediterranean, Asian, and Latin American diets, as well as providing recommendations suited to a vegetarian diet. They all recommend a low intake of red meat, with plants as the major source of fats and oils, as well as carbohydrates from minimally processed forms, generally as whole-grain products.

Food Information in Food Guide Diagrams

The amount of information about food that appears on food guide diagrams is variable. All of them include illustrations of some food items in each food group. Many countries have included food group names, or the recommended number of servings per day from each food group. Some provide word descriptors of how much to eat per day, such as "eat just enough, eat moderately, eat more, eat most," or recommended eating frequency i.e., "at every meal, daily, weekly, monthly". Oldways pyramids include lists of desirable species of whole grains, types of grain-based foods, sources of plant oils, and specific nuts and seeds, thereby reinforcing the importance of grains in general in some food groups. Also relevant to products included as grain-based foods is the appearance of legumes and nuts in the grains group in some guidelines and food guide diagrams, as well as in the vegetables group, dairy group, or meat, and alternates group in others. The USA pyramid provides symbols to indicate addition of fat and sugars to foods.

Quantitative Recommendations

To help consumers use food guide diagrams appropriately, many countries supplement their diagrams by adding quantitative information in a table or descriptive format. This information includes numbers of servings per day to eat from each food group, and serving sizes expressed as amounts for specific food types to eat per serving. These are listed in Table 1 for the grain-based foods only. It is important to make this information available to diagram users because many of them do not realize that the amount of food they eat is important. Determining the quantity of food to eat is a problem for many nutritional guideline and diagram users because they do not know/understand the units of measurement used for food. Therefore, they cannot convert number of servings and units of measurement for a serving, e.g., cups, grams, ounces, into amounts of food to eat. Effective educational programs are needed to teach the public where to find and how to use nutritional guidelines, food guide diagrams, and quantitative information about food.

Differences in culture, in food habits, and in foods available determine types of food, serving sizes and servings per day in the various countries (Table 1). At first sight, there appears to be a great diversity of

Table 1 Grain-based foods recommended in the respective national dietary guidelines

Country	*Grain serves/day*	*Examples of serve sizes for grain-based foods*
Australia	3–11	2 slices bread/$1\frac{1}{3}$ cup breakfast cereal/1 cup cooked rice or pasta
Britain	>5	30 g bread/30 g breakfast cereal/60 g rice, raw/cooked not specified
Canada	5–12	1 slice bread/30 g breakfast cereal/$\frac{1}{2}$ cup cooked rice or pasta
China	300–500 g	Total raw weight of any recommended grain-based foods altogether
Germany	250–350 g	Bread – 250–350 g, or cooked rice – 200–250 g, or potatoes – 250–300 g
Korea	4–5	3 slices bread (100 g)/90 g breakfast cereal/210 g cooked rice
USA	6–11	1 slice bread/1 oz breakfast cereal/$\frac{1}{2}$ cup cooked rice or pasta

Adapted from Painter J, Rah J-H, and Lee Y-K (2002) Comparison of international food guide pictorial representations. *Journal of the American Dietetic Association* 102: 483–489, © American Dietetic Association.

recommendations when comparing the number of servings per day for different countries. However, as just described, servings per day must be interpreted together with the respective sizes of the servings, which in Table 1 range between one and three slices of bread, and from 30 to 90 g of breakfast cereal, to determine the amount to be eaten. Interestingly, potatoes are considered a substitute for grains in Germany.

The USA Food Guide Pyramid – Agreement and Controversy

The current USA food guide pyramid, which was introduced in 1992, is presently being revised to match the concurrent revision of the dietary guidelines for Americans. Among the criticisms of this pyramid are opinions that it oversimplifies the nutrition message. According to Willett and Stampfer, writing in *Scientific American* in 2003, the pyramid is "grossly flawed." They wrote: "By promoting the consumption of all complex carbohydrates and eschewing fats and oils, the pyramid provides misleading guidance." They argued conversely, that not all fats are "bad," and that complex carbohydrates are not universally "good." Their suggested revision encouraged the consumption of "healthy fats" and avoidance of refined carbohydrates, butter, and red meat. Their revised pyramid retained whole-grain foods at the base, together with plant-derived oils, many of them from grains, e.g., from corn (maize), canola, sunflower, and peanut. The use of fats containing *trans* unsaturated fatty acids, which are formed in partially hydrogenated liquid vegetable oil when converted to a solid fat, and then used in firm margarines, baked products, and fried foods, is not recommended. Nuts and legumes are retained halfway up their pyramid. Foods high in complex carbohydrates such as white rice, white bread, pasta, and potatoes are placed at the apex, with the recommendation: "Use sparingly." These authors do not fully explain that fiber content and resistant starch are not greatly dissimilar for whole-grain and "white" (refined) foods. However, they do emphasize that "the best way to avoid obesity is to limit your total calories." Furthermore, they admit in conclusion that "uncertainties still cloud our understanding of the relation between diet and health."

The Oldways recommendations reinforce the concept of distinguishing between sources of fats and oils by recommending the greater consumption of oils from grains and nuts. However, the Oldways recommendations do not relegate the consumption of complex carbohydrates to the apex of the pyramid.

Conclusion

Despite some controversies, dietary guidelines generally emphasize the value of grain-based foods in the diet. This recommendation relates primarily to foods made from whole grains, because of their wider range of nutrients. In addition, the nutritional status of the diet is further enhanced by the inclusion of legumes and nuts, together with the variety of oils derived from grains such as maize and the oilseeds.

Effects of Food Processing

M Friedman, USDA-ARS, Albany, CA, USA

Introduction

In many foods, especially those from plants, a low level of an essential amino acid limits its nutritive value. These foods include cereals, which may be inadequate in the essential amino acids isoleucine, lysine, threonine, and tryptophan and legumes, which are often poor sources of methionine. These commodities are the principal sources of protein for much of the earth's rapidly growing population. The ratio of malnourished to adequately nourished humans will almost surely increase. For these reasons, and especially in view of the limited availability of high-quality (largely animal) protein to feed the present and future populations, improvement of food and feed quality is an important challenge to agricultural and nutritional sciences. Several approaches can be used to achieve such improvement. These include (1) fortification of foods with essential amino acids and good-quality protein supplements; (2) improvement of protein quality by plant breeding and genetic engineering; and (3) minimizing the damage to the nutritional value of proteins during food processing and storage. This brief article is largely limited to the last approach.

A variety of methods are used to process foods: if they are not edible, to render them so; to permit storage; to alter texture and flavor; to destroy microorganisms and other toxins. These methods include heating (baking, cooking, frying, microwaving), freezing, and employing high pH. It is a paradox of nature that the processing of foods can improve nutrition, quality, and safety; yet, occasionally these processing alternatives can lead to the formation of antinutritional and toxic compounds. These consequences of food processing result from molecular interactions among nutrients and with other food ingredients, both natural and added. Beneficial and adverse effects of food processing are of increasing importance to food science, nutrition, and human health. A better understanding of the molecular changes during food processing and the resulting nutritional and safety consequences is needed to optimize beneficial effects such as bioavailability, food quality, and food safety, and to minimize the formation and facilitate the inactivation of deleterious compounds. Such an understanding will encompass multidisciplinary studies of the chemistry, biochemistry, nutrition, and toxicology of food ingredients. Possible approaches to prevent the formation of deleterious food ingredients are also addressed.

This article uses examples largely based on studies by the author to illustrate general concepts. It describes compositional changes and the nutritional impact of two major food-processing conditions: pH and heat. The discussion outlines the following aspects of processing-induced formation of novel food ingredients and the resulting consequences for nutrition: protein–carbohydrate nonenzymatic browning reactions; heat-induced formation of acrylamide; inactivation of soybean inhibitors of digestive enzymes; formation of lysinoalanine and D-amino acids in food proteins; the stability of phenolic compounds to high pH; and factors which influence the bioavailability of essential amino acids.

Effect of Heat

Maillard Browning

Amino-carbonyl and related reactions of food constituents involve those changes commonly termed browning reactions. Specifically, reactions of amines, amino acids, peptides, and proteins with reducing sugars and vitamin C (nonenzymatic browning, often called Maillard reactions) and quinones (enzymatic browning) cause deterioration of food during storage and processing. The loss of nutritional quality is attributed to the destruction of essential amino acids, a decrease in digestibility, and inhibition of proteolytic and glycolytic enzymes. The production of toxic compounds may further reduce the nutritional value and the safety of foods. Studies in this area include influence of damage to essential amino acids on nutrition and food safety, nutritional damage as a function of processing conditions, and simultaneous formation of deleterious and beneficial compounds. These compounds include kidney-damaging Maillard reaction products, mutagens, carcinogens, antimutagens, antioxidants, antibiotics, and antiallergens (Tables 1–4 and Figures 1–3).

Maillard reactions may also result in formation of desirable flavors and antimicrobial compounds against

Table 1 Major sources of protein in the diet in developing and developed countries

Source	*Developing (%)*	*Developed (%)*
Cereals	58.8	29.1

human pathogens. Since the discovery of browning reactions by Maillard ~100 years ago, food scientists have been studying Maillard reactions and their effects on color, nutritional quality, and safety. In contrast, medical scientists have only been exploring relationships between *in vivo* browning and disease and aging for ~25 years. From such broad-based cross-fertilization of ideas, further progress that will benefit both food science and medicine can be expected.

Many individuals are sensitive to the antibrowning compound, sodium sulfite. Hence, the potential of sulfur amino acids to prevent browning was explored. The antioxidant and antitoxic effects of SH-containing amino acids such as cysteine, cysteine ethyl ester, N-acetylcysteine, and glutathione are due to a number of mechanisms including their ability to act as (1) reducing agents; (2) scavengers of reactive oxygen (free-radical traps); (3) destroyers of fatty acid hydroperoxides; (4) strong nucleophiles which can trap electrophilic compounds and intermediates; and (5) inducers of cellular detoxification. Thus, positive results were expected from an evaluation of sulfur amino acids to prevent the formation of browning products. These expectations were realized since it was found that SH-containing amino acids were nearly as effective as sodium sulfite in preventing browning in apples, potatoes, fruit juices, and protein-containing foods such as nonfat dry milk and barley and soy flours.

Although extensive efforts have been made to elucidate the chemistry of both desirable and undesirable compositional changes during browning, parallel studies on the nutritional and toxicological consequences of browning are limited. This is understandable since, in principle, each combination of a specific amino acid or protein with a particular carbohydrate needs to be investigated to understand the scope of the problem. Reported studies in this area include (1) influence of damage to essential amino acids, especially lysine, on nutritional quality; (2) effects of fortifying browning products with essential amino acids on recovery of nutritional quality; (3) nutritional damage as a function of processing conditions; (4) biological utilization of characterized browning compounds, such as fructosyl-L-lysine; and (5) formation of mutagenic and clastogenic products.

A number of investigators have examined the effects of the Maillard browning reaction on digestibility and nutritional quality. Experimental evidence has shown that loss of nutritional quality of heat-treated casein is related to decreased nitrogen digestibility rather than to simple destruction of essential amino acids. The influence of glucose and starch was minimal compared to observed effects of heat on casein alone under the conditions used. Glucose and, perhaps starch, augment protein degradation and loss of nutritional quality under moderate, dry-heat conditions. Further studies are needed to explain the molecular basis for the extent and nature of the heat-induced destruction of essential amino acids and the formation of indigestible browned and cross-linked products. These changes impair intestinal absorption and nutritional quality in general. Toxic compounds formed under these conditions might also modulate nutritional quality. Thus, such studies should differentiate antinutritional and toxicological interrelationships and develop means for preventing or minimizing the formation of deleterious compounds in foods.

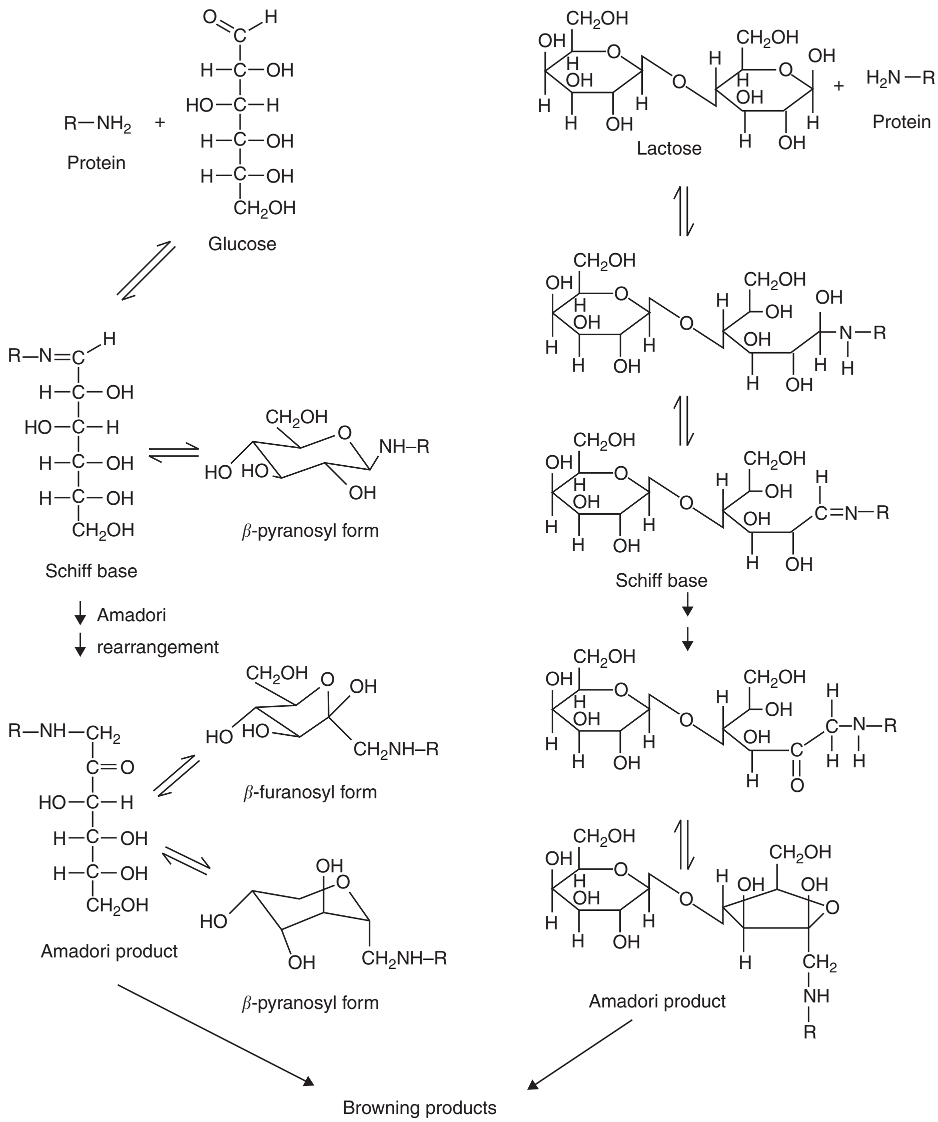

Figure 1 Pathways for Maillard nonenzymatic browning reactions of a protein with glucose and lactose.

Related studies showed that the phenolic compound chlorogenic acid decreased by ~100% in the crust fraction and 65% in the crumb fraction of a conventional baked muffin. Microwave baking reduced the chlorogenic acid content by 77% of the original. These results demonstrate that varying degrees of thermal destruction of chlorogenic acid and possibly other phenolic compounds can occur in a typical flour mix at ordinary baking temperatures.

Formation and Biological Effects of Acrylamide

Recent reports indicate that heat induces the formation of acrylamide ($CH_2{=}CH{-}CO{-}NH_2$) in food under conditions that also induce the formation of browning products. This observation stimulated interest in the underlying chemistry that may be responsible for the formation of acrylamide as well as the chemical and biochemical basis of the toxicological effects of this conjugated vinyl compound: it has been reported to be a neurotoxin, reproductive toxin, and animal carcinogen.

It appears that the free amino acid asparagine and free glucose are major precursors of acrylamide. Selecting cultivars for food uses that contain low levels of asparagine and/or glucose may result in low-acrylamide processed foods.

In extensive studies, on the reactions of conjugated vinyl compounds including acrylamide, acrylonitrile, and methyl acrylate with wheat gluten, designed to prepare derivatives of potential industrial use, it was found that SH groups of cysteine residues, as well as, the -NH_2 group of lysine side chains has a strong avidity for the double bond of acrylamide (Figure 4).

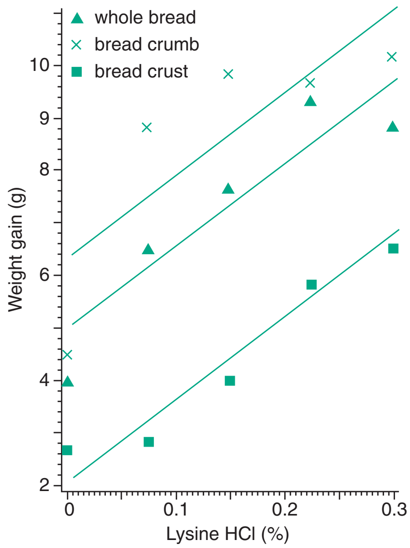

Figure 2 Weight gain in mice after 14 days fed whole bread, bread crumb, and bread crust supplemented with lysine before baking.

Seminal studies conducted in this area provide a chemical basis for the biological effects of acrylamide and its reactive epoxide metabolite, glycidamide, *in vivo*. The *in vivo* reactions involve biological alkylation reactions of proteins such as hemoglobin, enzymes, and DNA. Understanding the chemistry of formation of acrylamide during food processing and its reactions both *in vitro* and *in vivo* will make it possible to design effective means to prevent or arrest undesirable consequences of acrylamide in the diet. Research needs in this area include the following:

1. Does prevention of food browning by sulfur amino acids and peptides described above also prevent acrylamide formation?
2. Since acrylamide can react with lysine residues of proteins, do low-lysine proteins (wheat gluten, zein) produce more acrylamide than high-lysine proteins (casein, soy protein, meat proteins)?
3. Will replacement of corn meal with high-lysine corn meal result in less acrylamide in potato chips and tortillas?

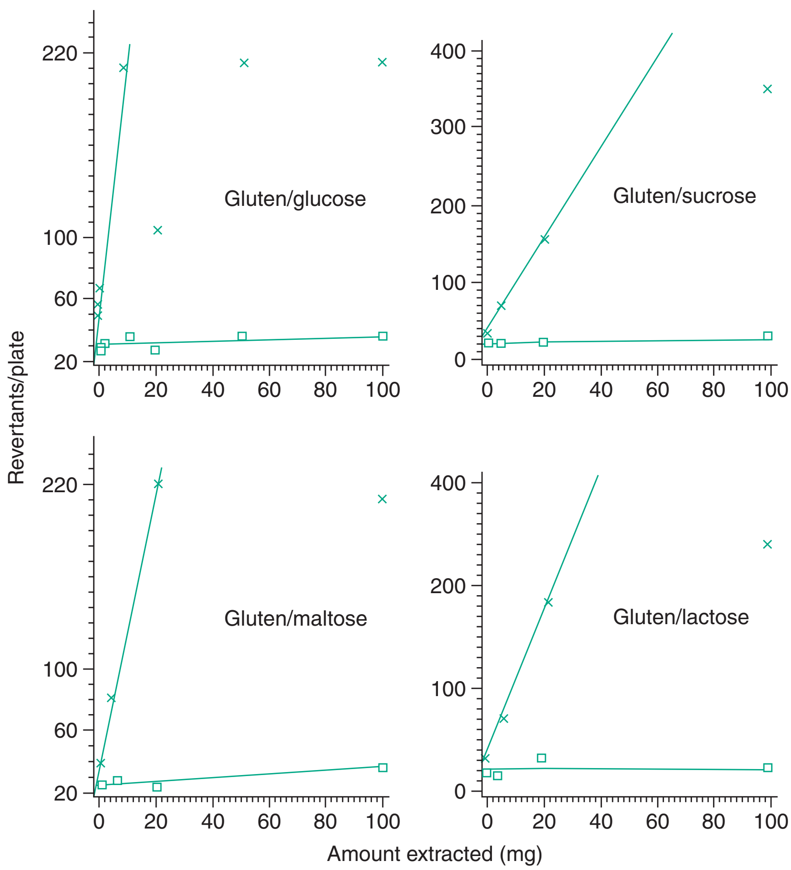

Figure 3 Mutagenicity in the Ames test of extracts of wheat gluten–carbohydrate mixtures heated under crust-baking conditions. □ = unheated; x = heated.

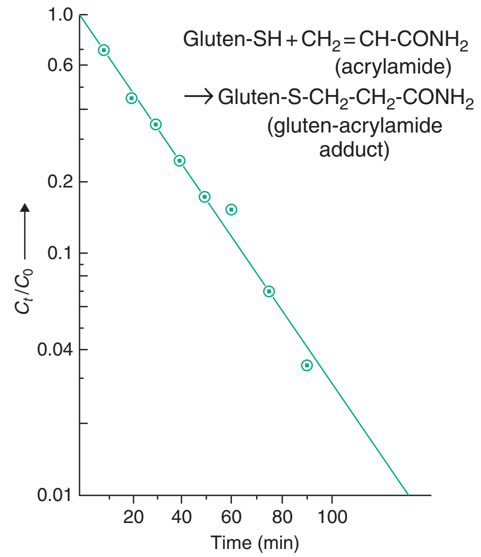

Figure 4 Reaction rate of wheat gluten SH groups with acrylamide at 30°C. C_0 = initial concentration; C_t = concentration at time *t*.

4. Do concurrent heat-induced Maillard browning products and other food ingredients affect the safety of acrylamide after consumption?
5. Will the use of wheat flour containing low levels of asparagine and/or glucose result in low-acrylamide baking products?

It is also relevant to note that in the course of studies on reactions of acrylamide and related compounds with proteins, it was found that vinylpyridine can be used to selectively modify protein SH groups. This reaction has been widely adopted and used to stabilize cereal proteins, facilitating their separation and isolation from extracts of wheat, corn, and barley by HPLC and related chromatographic methods.

Ascorbate Browning

When a nutritionally complete, low-protein basal diet containing 10% casein was supplemented with 20% protein from unheated casein, wheat gluten, or soybean, test mice exhibited a significantly increased weight gain. In contrast, weight gain was markedly reduced when the supplement was soy protein or gluten heated at 200°C or 215°C for 72 min in the dry state (simulated crust baking). Baked casein was nonnutritive. Adding carbohydrates to gluten during heating prevented subsequent growth inhibition. After heating with sodium ascorbate (but not L-ascorbic acid), soy protein (at 200°C) and gluten (at 215°C) completely prevented growth when added to the basal diet. Growth inhibition was also aggravated by a heated casein-ascorbate mixture, but less than with the other proteins. The extent of nutritive damage increased sharply with heating temperature in the range 180–215°C, and with sodium ascorbate concentration in the range 1–20%. It was also found that sodium ascorbate heated with amino acids, especially tryptophan, results in the formation of antinutritional compounds.

The reduced weight gain of mice, fed a nutritionally adequate diet supplemented with these materials, suggests that heating induces the formation of nutritionally antagonistic or toxic compounds that interfere with essential metabolic pathways such as digestion, transport, absorption, and utilization of nutrients. Further studies of the chemical basis of these effects may be more conveniently performed with tryptophan or other amino acid/ascorbate mixtures than with the more complex protein/ascorbate blends, since the heat-induced products may be easier to isolate and characterize.

Heating experiments conducted by the author used proportionately much more sodium ascorbate than is used in thermal food processing to improve bread-dough characteristics such as loaf volume and bread texture, and to inhibit nitrosamine formation in bacon. However, since results do not rule out possible cumulative biological effects, additional studies are needed to determine whether consumption of low levels of the heat-derived compounds can be a human health hazard.

The results suggest that deleterious material formed during heating of gluten or soy protein, and to a lesser extent casein, may represent the degradation of protein to nitrogenous materials without nutritional value. At the nominal protein level, such materials would represent a severe metabolic burden (toxic effect) when fed to the animal, which must then eliminate them. The protective effect of carbohydrates in diminishing the formation of toxic gluten is interpreted as a thermochemical volatilization of deleterious products, while sodium ascorbate appears to reduce vaporization.

These considerations suggest the need:

1. to characterize the compound(s) in heated protein and amino acid–sodium ascorbate mixtures that may be responsible for the observed growth inhibition;
2. to determine the safety of the pure compounds in laboratory animals and measure their prevalence in commercial foods in order to define possible human risk;
3. to carry out studies with related food ingredients such as sodium citrate, sodium gluconate, and sodium glutamate in order to define the mechanism of this type of growth inhibition;

4. to devise processing conditions to prevent the formation of the growth inhibitors in food; and
5. to use ascorbic acid rather than sodium ascorbate in baking formulations.

Food Allergenicity

As noted earlier, carbohydrates interact with proteins to form Maillard browning products. The effects of these transformations on the antigenicity of the Kunitz soybean trypsin inhibitor (KTI) with two monoclonal antibodies were studied. Solid mixtures of KTI and carbohydrates were heated in an oven at 120°C, dialyzed, freeze-dried, and analyzed by enzyme-linked immuno-sorbent assay (ELISA). Glucose, lactose, and maltose decreased the antigenicity of KTI to levels 60–80% lower than those observed in a control sample heated without carbohydrate. Starch was less effective than the three reducing sugars. The decrease was rapid, occurring within 10 min when glucose was heated with KTI, with retention of 60% of the chemically available lysine. Longer heating times increased browning and reduced the level of available lysine in KTI, without further reducing antigenicity. The results suggest that relatively mild conditions of heating food proteins with carbohydrates can reduce the antigenicity of the protein and possibly modify sites known to elicit allergenic responses. That these reactions can also introduce new antigenic determinants into a food protein should be noted.

Inactivation of Inhibitors of Digestive Enzymes

Soy protein is increasingly important in the human diet. However, soy protein is not an ideal protein since it is deficient in the essential amino acid methionine. The content of another essential amino acid, lysine, is higher than that of wheat protein but lower than that of milk protein casein. Adverse nutritional and other effects following consumption of raw soybean meal have been attributed to the presence of endogenous inhibitors of digestive enzymes, lectins, and to poor digestibility. To improve the nutritional quality of soy foods, inhibitors are generally inactivated by heat treatment or eliminated by fractionation during food processing. Most commercially heated meals still retain up to 20% of the Bowman-Birk (BBI) and Kunitz (KTI) inhibitors of digestive enzymes.

The content and heat stability of protease inhibitors of a standard cultivar (Williams 82) and an isoline lacking the KTI were measured by using enzyme inhibition and ELISA. Steam heating of the isoline flour (121°C, 20 min) resulted in a near-zero level of trypsin inhibitory activity, while 20% remained in the Williams 82 sample. The raw soy flour prepared from the isoline was nutritionally superior to the raw flour prepared from the standard variety, as measured by protein efficiency ratio (PER) and pancreatic weights. The increased PER was likely due to the lower level of trypsin inhibitor activity in the isoline. Steam heating the flours for up to 30 min at 121°C progressively increased the PER for both strains. Less heat was needed to inactivate the inhibitors in the isoline than in the standard cultivar.

Related studies showed that treating raw soy flour with cysteine, N-acetyl-L-cysteine, or reduced glutathione introduces new half-cystine residues into native proteins, with a corresponding improvement of nutritional quality and safety. The proteins are modified through formation of mixed disulfide bonds among added thiols, protease inhibitors, and structural protein molecules. This leads to decreased inhibitory activity and increased protein digestibility and nutritive value. The SH-containing amino acids also facilitate heat inactivation of hemagglutinins (lectins) in lima bean flour. Exposure of raw soy flour to sodium sulfite was also nutritionally beneficial.

Naturally occurring enzyme inhibitors, such as BBI in which every sixth amino acid residues is cystine, also have beneficial effects such as prevention of development of colon cancer in mice. Although the molecular basis for such beneficial effects needs to be ascertained, one possibility is that the inhibitors or inhibitor–protease complexes act as free radical traps, whereby the free electrons on damaging oxygen radicals are transferred or dissipated to the sulfur atoms of the sulfur-rich inhibitors or complexes. These considerations suggest the need for further studies to learn more about possible beneficial effects of plant protease inhibitors in relation to sulfur amino acids.

Effect of pH

General Aspects

Exposure of food proteins to heat and high pH induces two major chemical changes: racemization of all L-amino acids to D-isomers and concurrent formation of lysinoalanine. Racemization of L-amino acids residues to their D-isomers in food and other proteins is pH-, time-, and temperature dependent. Although racemization rates of the 18 different L-amino acid residues in a protein vary, the relative rates in different proteins are similar. The diet contains both processing-induced and naturally formed D-amino acids. The latter include those found in microorganisms, plants, and marine invertebrates. Racemization impairs digestibility and nutritional quality. The nutritional utilization of different D-amino acids varies widely in animals and humans. In addition, some D-amino acids may be deleterious (Tables 5 and 6 and Figures 5–8).

Table 5 Effect of pH on the lysine and lysinoalanine (LAL) content of wheat gluten

Mole (%)	*Control*	*pH 9.6*	*pH 10.6*	*pH 11.2*	*pH 12.5*
Lys	1.33	1.40	1.16	0.96	0.94
LAL	0.00	0.00	0.26	0.42	0.76

Table 6 Digestibility and net protein utilization (NPU) of toasted and alkali-treated soy proteins in rats

Diet	*Digestibility (%)*	*NPU (N retained/N intake) × 100*
Casein	98.3	80.6
Toasted soy	97.0	62.4
Alkali-treated soy	83.2	28.3

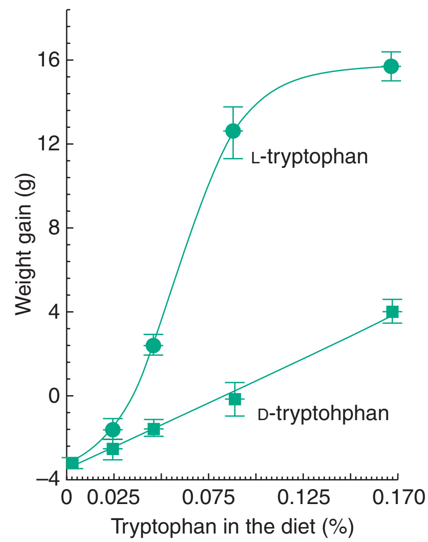

Figure 7 Comparison of weight gain in mice fed L- and D-tryptophan as part of an all-amino-acid diet.

Although proteins containing D-amino acids can be hydrolyzed at peptide bonds, the hydrolysis rates may be slower than those for corresponding native proteins. Such changes can impair the nutritional quality and safety of foods by generating nonmetabolizable and biologically nonutilizable forms of amino acids, creating D–D, D–L, and L–D peptide bonds partly or fully inaccessible to proteolytic enzymes, and forming nutritionally antagonistic as well as toxic compounds. Furthermore, these altered proteins may compete with proteins, which do not possess racemized amino acids, for the active site of digestive proteases in the gut and thus render the unracemized proteins also less nutritionally available. A need exists to develop a better understanding of the roles of D-amino acids in human nutrition. For example, it is not known whether D-amino acids and peptides can change the microbial flora of the digestive tract.

Racemization of L-Amino Acids to D-Isomers

Since the early 1900s, alkali and heat treatments have been known to racemize amino acids. As a result of food processing using these treatments, D-amino acids are continuously consumed by animals and man. Because all of the amino acid residues in a protein undergo racemization simultaneously, but at differing rates, assessment of the extent of racemization in a food protein requires quantitative measurement of at least 36 optical isomers, 18 L and 18 D. Analytically, this is a difficult problem.

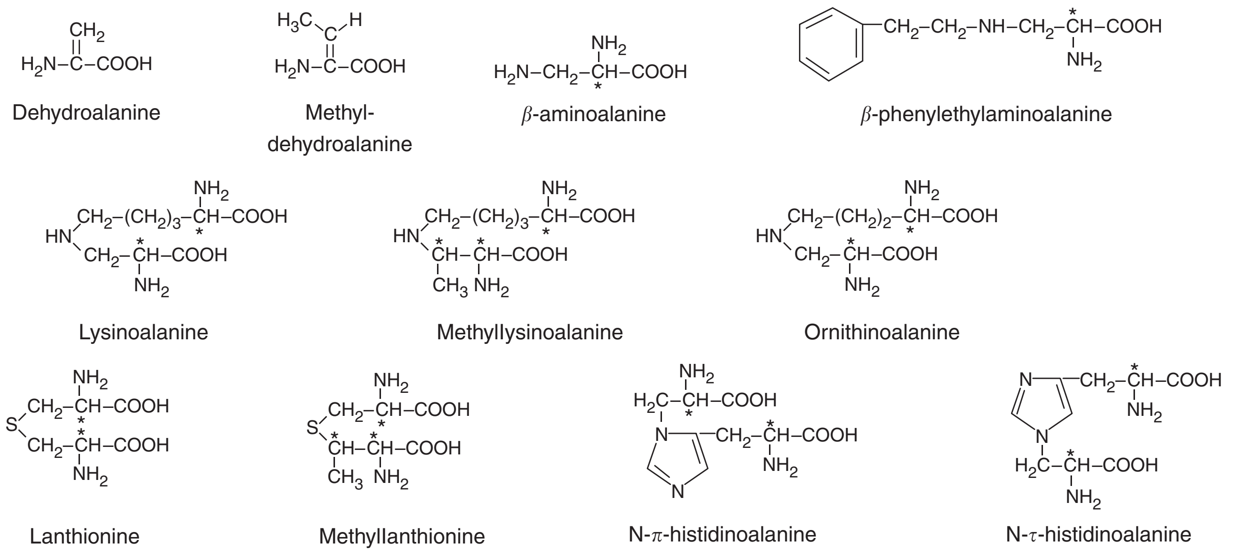

Figure 8 Structures of dehydro- and cross-linked amino acids formed during exposure of food proteins to heat and high pH. Asterisks indicate the number of asymmetric carbon atoms.

Racemization of an amino acid proceeds by removal of a proton from the α-carbon atom to form a carbanion intermediate. The carbanion, having lost the original asymmetry of the α-carbon, recombines with a proton from the environment to regenerate a tetrahedral structure. The reaction is written as

$$\text{L-amino acid} \underset{k'_{rac}}{\overset{k_{rac}}{\rightleftharpoons}} \text{D-amino acid}$$

where k_{rac} and k'_{rac} are the first-order rate constants for the forward and reverse racemization of the stereoisomers. The product is racemic if recombination can take place equally well on either side of the carbanion, giving an equimolar mixture of L- and D-isomers.

Because the structural and electronic factors that facilitate the formation and stabilization of the carbanion intermediate are unique for each amino acid, it follows that the reaction rate for the isomerization of each amino acid is also unique. Thus, the inductive strengths of the R-substituents have been invoked to explain differing racemization rates in the various amino acids. Plotting racemization for individual amino acids in casein and soybean proteins against the inductive parameters clearly demonstrates strong correlations (Figure 5).

Two pathways are available for the biological utilization of D-amino acids: (1) racemases or epimerases may convert D-amino acids directly to L-isomers or to (DL) mixtures; or (2) D-amino-acid oxidases may catalyze oxidative deamination of the α-amino group to form α-keto acids, which can then be specifically reaminated to the L-form. Although both pathways may operate in microorganisms, only the second has been demonstrated in mammals.

The amounts and specificities of D-amino acid oxidase are known to vary in different animal species. In some, the oxidase system may be rate limiting in the utilization of a D-amino acid as a source of the L-isomer. In this case, the kinetics of transamination of D-enantiomers would be too slow to support optimal growth. In addition, growth depression could result from nutritionally antagonistic or toxic manifestations of D-enantiomers exerting a metabolic burden on the organism.

The nutritional utilization of different D-amino acids varies widely, both in animals and humans. In addition, some D-amino acids may be deleterious. For example, although D-phenylalanine is nutritionally available as a source of L-phenylalanine, studies by the author have shown that high concentrations of D-tyrosine inhibit the growth of mice. The antimetabolic effect of D-tyrosine can be minimized by increasing the L-phenylalanine content (protein bound, or free) of the diet. Similarly, L-cysteine has a sparing effect on L-methionine when fed to mice; however, D-cysteine does not. The wide variation in the utilization of D-amino acids is exemplified by the fact that D-lysine is not utilized as a source of the L-isomer for growth. The utilization of methionine is dose-dependent, reaching 76% of the value obtained with L-methionine. Both D-serine and the mixture of L–L and L–D isomers of lysinoalanine induce histological changes in the rat kidneys. D-tyrosine, D-serine, and lysinoalanine are produced in significant amounts under the influence of even short periods of alkaline treatment.

Whether the biological effects of D-amino acids vary depending on their consumption in the free state or as part of a food protein is unresolved. Indications are that L—D, D—L, and D—D peptide bonds in food proteins may not hydrolyze as readily as naturally occurring L—L peptide bonds. Possible metabolic interaction, antagonism, or synergism among D-amino acids *in vivo* also merits further study. The described results with mice complement related studies with other species and contribute to the understanding of nutritional and toxicological consequences of ingesting D-amino acids. Such an understanding will make it possible to devise food-processing conditions to minimize or prevent the formation of undesirable D-amino acids in food proteins and to prepare better and safer foods.

Lysinoalanine and Related Amino Acids

Heat and alkali treatment of foods, widely used in food processing, results in the formation of dehydro- and cross-linked amino acids such as dehydroalanine, methyldehydroalanine, β-aminoalanine, lysinoalanine (LAL), ornithinoalanine, histidinoalanine (HAL), phenylethylaminoalanine, lanthionine (LAN), and methyl-lanthionine present in proteins (Figure 8). The presence of LAL residues along a protein chain decreases nutritional quality in rats (Table 6) and primates but enhances nutritional quality in ruminants. LAL, HAL, and LAN also occur in certain peptide antibiotics (cinnamycin, duramycin, nisin, and subtilin) and in body organs and tissues (aorta, bone, collagen, dentin, eye cataracts), where their formation may be a function of the aging process.

Detailed studies revealed that base-catalyzed synthesis of lysinoalanine proceeds by the addition of the ε-NH_2 group of lysine to the double bond of a dehydroalanine residue. This residue is derived from cysteine and/or serine (Figure 9). From a nutritional standpoint, lysinoalanine formation results in a decrease of the essential amino acid lysine, and the semiessential amino acid cystine, as well as in a decrease in digestibility of the modified protein.

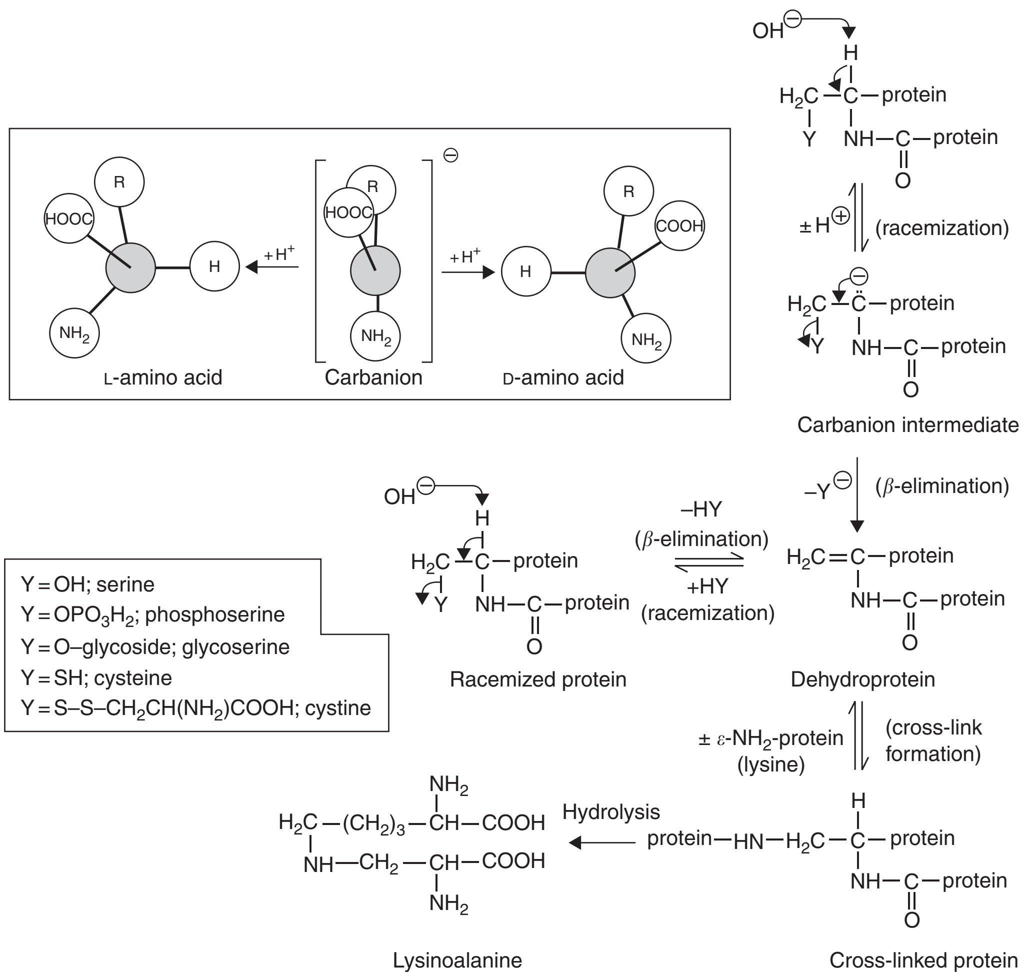

Figure 9 Mechanism of hydroxide ion-catalyzed racemization and lysinoalanine formation in food and other proteins.

In rats, studies have found histological changes in the kidneys related to dietary exposure to this substance, either isolated or as part of intact proteins. The lesions are located in the epithelial cells of the straight portion of the proximal renal tubules and are characterized by enlargement of the nucleus and cytoplasm, increased nucleoprotein content, and disturbances in DNA synthesis and mitosis.

Because of these observations, concern has arisen about the safety of foods that contain lysinoalanine and related dehydroalanine-derived amino acids known to produce similar lesions. However, since the mechanism by which these compounds damage the rat kidney is unknown, it is difficult to assess the risk to human health caused by their presence in the diet.

Lysinoalanine has two asymmetric carbon atoms, making possible four separate diastereoisomeric forms: LL, LD, DL, and DD. Its structure suggests that it should have excellent chelating potential for metal ions, a property that may be relevant to its toxic action. Accordingly, its affinity towards a series of metal ions, of which copper (II) was chelated the most strongly has been examined (Figure 6). On this basis, it was suggested that a possible mechanism for kidney damage in the rat involving lysinoalanine's interaction with copper within the epithelial cells of the proximal tubules.

The apparent direct relationship between the observed affinities of the two lysinoalanine isomers for copper (II) ions *in vitro* and their relative toxic manifestation in the rat kidney is consistent with the hypothesis that lysinoalanine exerts its biological effect through chelation of copper in body fluids and tissues. Limited studies on the binding of LL- and LD-lysinoalanines to cobalt (II), zinc (II), and other metal ions imply that lysinoalanine could also influence cobalt utilization *in vivo*.

Factors, which minimize lysinoalanine formation, include the presence of cysteine, N-acetylcysteine, and reduced glutathione, sodium sulfite, ammonia, biogenic amines, ascorbic, citric, and malic acids, glucose, dephosphorylation of O-phosphoryl esters, and acylation of ε-NH_2 groups of lysine.

Stability of Plant Phenolic Compounds

Phenolic compounds are secondary metabolites found in cereals, coffee beans, fruits, olives, vegetables, and tea leaves. A study on the stability of structurally different phenolic compounds in buffers in the pH range 3–11 revealed that caffeic, chlorogenic, and gallic acid were not stable to high pH. By contrast, catechin, epigallocatechin, ferulic acid, rutin, and cinnamic acid resisted pH-induced degradation. The results suggest that if a specific phenolic compound is found to be unstable under food-processing conditions, it may not be effective as an antioxidant, anticarcinogen, or antibiotic when present in foods subjected to heat or high pH.

Bioavailability of Amino Acids

Lysine and Derivatives

Wheat gluten, the major protein in many baking formulations, is considered a poor-quality protein, primarily because it has insufficient amounts of two essential amino acids: lysine, the first-limiting amino acid, and threonine, the second-limiting one. To compensate for the poor quality of most cereal proteins such as gluten, the minimum recommended daily allowance (RDA) for these proteins has been set at 65 g, compared to 45 g for good-quality proteins such as casein.

During baking, the mixture of protein, carbohydrate, and water plus additives in dough is exposed to two distinct transformations. Desiccation of the surface on exposure to temperatures reaching 215°C produces the crust. The crust encloses part of the dough in steam phase at ~100°C, resulting in the formation of the crumb.

Because lysine's ε-amino group interacts with food constituents to make it nutritionally less available, the baking process further reduces the dietary availability and utilization of lysine, especially in the crust, which makes up ~40% of the bread by weight. Many such interactions have been described including

1. the reaction of the amino group with carbonyl groups of sugars and fatty acids to form Maillard browning products;
2. the formation of cross-linked amino acids such as lanthionine, lysinoalanine, and glutamyllysine;
3. the interaction with tannins and quinones; and
4. steric blocking of the action of digestive enzymes by newly introduced cross-links, as well as native ones such as disulfide bonds.

Because these reactions of lysine with other dietary components may lead to protein damage and to the formation of physiologically active compounds, an important objective of food science and nutrition is to overcome these effects.

In principle, it is possible to enhance the nutritional quality of bread by amino acid fortification. A major problem encountered when free lysine is used to fortify foods is that the added amino acid can itself participate in browning and other side reactions.

To assess whether glutamyllysine, which undergoes less browning than does lysine, can serve as

a nutritional source of lysine, comparisons were made of the growth of mice fed (1) an amino acid diet in which lysine was replaced by four dietary levels of glutamyllysine; (2) wheat gluten diets fortified with lysine; (3) a wheat bread-based diet (10% protein) supplemented before feeding with lysine or glutamyllysine, not cobaked; and (4) bread diets baked with these levels of lysine or glutamyllysine. For the amino acid diet, the relative growth response to glutamyllysine was about half that of lysine. The effect of added lysine on the nutritional improvement of wheat gluten depended on both lysine and gluten concentrations in the diet. With 10% and 15% gluten, 0.37% lysine hydrochloride produced markedly increased weight gain. Further increase in lysine hydrochloride to 0.75% proved somewhat detrimental to weight gain. Lysine hydrochloride addition improved growth when 20–25% gluten was present in the diet and did not prove detrimental at 0.75% level. For whole bread, glutamyllysine served nearly as well as lysine to improve weight gain. The nutritive value of bread crust, fortified or not, was markedly less than that of crumb or whole bread (Figure 2). Other data showed that lysine or glutamyllysine at the highest level of fortification, 0.3%, improved the protein quality (PER) of crumb over that of either crust or whole bread, indicating a possible greater availability of the second-limiting amino acid, threonine, in crumb. These data and additional metabolic studies with [U-^{14}C] glutamyllysine suggest that glutamyllysine, cobaked or not, is metabolized in the kidneys and utilized *in vivo* as a source of lysine; this and related peptides merit further study as sources of lysine in low-lysine foods.

Amino acids are used both metabolically, as building blocks for protein biosynthesis, and catabolically, as energy sources. Catabolism for most amino acids proceeds through transamination pathways; the exceptions are lysine and threonine. Specific enzymes catabolize these nutritionally limiting amino acids: threonine dehydratase acts on threonine and lysine ketoglutarate reductase on lysine. The concentrations of these enzymes in the liver of rats are subject to adaptive responses that control the utilization of these two amino acids. Although both enzymes are induced by feeding diets high in protein, rats differ in the mechanism of the adaptive response to high-protein diets and to diets whose threonine or lysine content is less than that needed for growth. Thus, reductase falls to very low levels in the liver of rats fed wheat gluten. This appears to be an adaptive response conserving body lysine. At the same time, catabolism of body proteins increases, producing endogenous lysine needed for survival. These considerations imply that as the level of wheat gluten in the diet decreases, lysine is no longer the limiting amino acid. Total protein or some other amino acid then becomes limiting.

In contrast to the apparent mechanism of lysine catabolism, threonine dehydratase does not appear to be substrate induced. Therefore, when lysine is the limiting amino acid, the catabolic enzyme falls to low levels and lysine is apparently conserved at the expense of body proteins. Loss of tissue proteins is much less when a diet low in threonine is fed, since the level of threonine dehydratase does not seem to be significantly affected by the protein or threonine content of the diet. Additional studies are needed to establish whether the catabolic enzyme patterns in mice parallel those of humans.

The results also show that mice provide a good animal model to study protein quality of native, fortified, and processed wheat proteins. Mouse bioassays have a major advantage in applications to label foods for protein nutritional quality. They require about one-fifth of the test material needed for rats and can be completed in 14 days instead of 28 days. They are especially useful to evaluate nutritional and safety impacts of new food ingredients formed during processing and of new plants and plant parts, when amount of material available for bioassays is limited.

Methionine and Derivatives

The low content of the essential amino acid L-methionine limits the nutritive value of many food proteins of plant origin. These include soybeans and other legumes. The problem is further compounded for two reasons. First, during food processing and storage L-methionine and other amino acids are chemically modified, further reducing nutritional quality. In the case of methionine, such modifications include oxidation to methionine sulfoxide and methionine sulfone, racemization to D-methionine, and degradation to compounds with undesirable flavors. Second, protein-bound methionine in some plant foods is poorly utilized, presumably because of poor digestibility.

A related aspect is the widespread use of L-methionine to fortify low-methionine foods in order to improve nutritional quality. Because of the reported antinutritional or toxic manifestations of high levels of free methionine in the diet, a need exists to find out whether methionine analogs and derivatives lack the apparent toxicity of L-methionine and whether they can be used as methionine substitutes in the diet.

As part of a program to evaluate the nutritional and toxicological potential of novel amino acids formed during food processing, weight gain in mice fed amino acid diets containing graded levels of L-methionine and 16 methionine derivatives, isomeric dipeptides,

and analogs was compared. Because the mice received no other source of sulfur amino acids, the results reflect the ability of each of the compounds to meet the animals' entire metabolic demand for dietary sulfur amino acids, relative to that for L-methionine. The results imply that some methionine dipeptides or analogs may be better candidates for fortifying foods than L-methionine.

The data for mice demonstrate that

1. the assay is highly reproducible, exhibits excellent dose-response characteristics, and yields useful estimates of relative potency for the 16 methionine analogs; and
2. somewhat rigorous control of concentration may be required for dietary supplementation with L-methionine in order to achieve maximum nutritional benefit while preventing toxicity problems.

This constraint may be alleviated or avoided by using one or more analogs as alternatives. Whether these compounds will also alleviate the reported adverse flavor aspects of sulfur amino acid supplementation associated with methionine when it is added to foods awaits further study.

Tryptophan and Derivatives

The essential amino acid tryptophan contributes to normal growth and protein synthesis and participates in numerous biochemical processes. Since tryptophan is a nutritionally second-limiting amino acid in maize, and since cereals and processed foods are increasingly used to meet human dietary needs, it is of paramount importance to develop an understanding of thermally induced changes in tryptophan in order to improve the quality and safety of our food supply.

The stability of free or protein-bound tryptophan during processing and storage depends on temperature and the presence of oxygen or other oxidizing agents, especially lipid peroxides, and radiation. In the absence of oxidizing agents, tryptophan is a stable amino acid, even in strongly basic or acidic conditions. Free or bound tryptophan is relatively stable during heat treatments such as industrial or home cooking in the presence of air or steam sterilization. Only severe treatments cause a significant degradation of this amino acid. In the presence of carbonyl compounds and/or at high temperatures, however, carboline formation occurs. Both carbolines and tryptophan-derived nitroso compounds are potential carcinogens. Tryptophan losses during food processing cannot always be monitored because of the lack of reliable analytical methods.

The losses in tryptophan bioavailability during heat treatment such as home cooking or industrial sterilization appear less important than other detrimental effects, particularly on lysine or methionine. Some of the reported variabilities in the utilization of D-tryptophan could be due to the fact that the value (potency), of D-tryptophan as a nutritional source of L-tryptophan is strongly dose-dependent (Figure 7).

Possible consequences for nutrition, food safety, and human health of halogenated tryptophans, light-induced tryptophan adducts; tryptophan-derived carbolines, and tryptophan-induced eosinophilia myalgia are not well understood.

Conclusions

This article shows that pH, heat, and oxygen have both beneficial and adverse effects on many nutrients. To maximize beneficial effects, future studies should emphasize the prevention of browning and the consequent antinutritional and toxicological manifestations of browning products and acrylamide in whole foods. Many of the safety concerns cited, especially those of genotoxic potential, are based on *in vitro* data that may not always be relevant to *in vivo* effects following the consumption of whole food products containing the browning-derived constituents. The presence of other dietary constituents in the food and the process of digestion and metabolism can be expected to decrease or increase the adverse manifestations of browning and heat-induced products. For nutrition and food safety, possible consequences of chelation of nutritionally essential trace materials to processing-induced food ingredients, beneficial effects of processing on food allergy, the immune system, and food microbiology and differentiating adverse and beneficial effects of heat and oxygen on lipids and vitamins also merit study.

A better understanding of the chemical changes during food processing will permit optimizing beneficial effects such as bioavailability, food quality, and safety, and to minimize the formation and facilitate removal of deleterious mutagens, carcinogens, allergens, pathogens, and other toxins. Future study should differentiate antinutritional and toxicological relationships, develop a relative biological potency scale of new food ingredients formed during food processing, define combined potencies of browning and other products, and develop means to prevent the formation of the most toxic compounds.

Mineral Composition

E Asp, University of Minnesota, South Anoka, MN, USA

Introduction

Minerals are food components that are required to establish and maintain life processes in plants and humans. Whole grains, grain-based foods, legumes, and seeds are important dietary sources of minerals. In plants and the human body, minerals interact with one another and with other nutrients and components to provide beneficial effects. In grains, minerals enable plants to grow and produce mineral-rich kernels and seeds used as food by humans. When dietary intakes include grain-based foods, they supply minerals to maintain the health and wellness of the human body.

As quantitative information about the content of minerals, vitamins, and other nutrients in food became available with improved accuracy of analytical techniques and instruments, food composition tables have been developed to present the data. Such a table for minerals, vitamins, and other nutrients and food components in selected grains and grain-based foods is available in **Appendix**: Grain Composition Tables. The purpose of this article is to discuss and compare the mineral composition of grains and grain-based foods. Examples have been incorporated from the data provided in the above-mentioned appendix.

Characteristics of Minerals

Minerals are inorganic elements that are needed in very small amounts by plants, animals, and humans. For example, in plants, minerals function to promote growth. Magnesium is an important component of the green pigment, chlorophyll, involved in photosynthesis. Minerals give the human body structure; they are needed for growth and development, and are components of organs and fluids; and they serve as cofactors for enzymes. Minerals also participate in regulating nerve impulses, acid–base balance in fluids, and contraction and relaxation of muscles (Table 1). Mineral deficiencies or excesses in humans may result in major health problems. Long-term deficiency in calcium intake is known to be a major contributor to osteoporosis, often called "brittle bone" disease. Deficient intake of iron commonly results in iron-deficiency anemia. An excess of sodium intake has been associated with high blood pressure in some people.

Minerals are identified by their names or chemical abbreviations (Table 1 and **Appendix**: Grain Composition Tables). They are classified as major minerals and trace minerals, depending on the amounts required by the human body. Major minerals are essential elements that must be supplied in human food intakes. Their recommended intakes are >100 mg per day (Table 1). They are found in abundant amounts in foods, and their functions in the body are well understood. Trace minerals are also essential elements; however, their recommended intakes are <100 mg per day. They are found in small amounts in food sources. Overall, the importance of their functions has been identified primarily since the second half of the twentieth century, and the functions of some trace minerals are less well understood than

Table 1 Characteristics of minerals in grains and grain-based foods[a]

[c] AI = adequate intake.
[d] Recommended intake.

those of major minerals. Research continues to clarify functions of minerals in plants, animals, and humans.

Minerals are stable to heat and are not destroyed when foods are cooked. Although they are insoluble in water, when plant foods are cooked using liquid, minerals can be physically lost from cut surfaces of the tissue or leached from the food into the cooking liquid. These minerals remain intact and can be recovered by using the cooking liquid. Conversely, when cooked in already mineral-rich water, foods can absorb more minerals, thereby increasing their mineral contents.

Grain Structure and Location of Minerals

Whole grains, legumes, and seeds make important contributions to the minerals in food intakes. Their mineral contents are obtained from the soils in which they are grown. Dietary intake of minerals may not be fully absorbed by the body. Bioavailability of plant minerals, i.e., "the level of absorption of a consumed nutrient," is affected by how tightly they are bound in plant tissue. Such minerals are difficult to extract from plant tissue during digestion.

Cereal grain kernels have three major components: bran, germ, and endosperm. Bran, the outer covering of the kernel, is composed of several layers. The aleurone layer of the bran is an important layer next to the starchy endosperm, the largest portion of the kernel. The germ or embryo is the source of the new plant in a germinating kernel. All grains are similar in the types of tissues they contain and in the molecular and cellular organization of their tissues.

Minerals are concentrated in different parts of the kernel where they work together to activate a wide variety of reactions and interactions. Each compound in the grain is stored in a specific structural location.

The extractability of some of these compounds from storage within grains is easy, while others are difficult to remove from the storage locations.

The bran and germ aleurone cells contain most of the minerals and other nutrients in the grain, and that is where metabolic activities occur. Wheat aleurone cells contain the highest proportion of the calcium, magnesium, potassium, sodium, and iron in the grain. The starchy endosperm contains the second largest proportion of minerals in the kernel. Whole cereal grains contain phytic acid in the bran layers, which binds minerals and thereby decreases their bioavailability during digestion. Other sources of phytic acid are pulses, oilseeds, and nuts.

Effects of Grain Processing on Minerals

Grains are unique because they are seldom eaten in the raw state. For optimum benefits from their constituents, grains are processed in many ways to produce functional ingredients to make nutritious and palatable grain-based foods. Commercial processing of grains disrupts the organization of the kernels to release minerals and other constituents from storage in the aleurone cells and to make the starch of the endosperm available for digestion. Effects of processing differ for each process and grain combination. Processing techniques used include grinding or crushing the entire kernel of the grains into whole-grain flours, or milling to separate bran, germ, and endosperm of the kernel to obtain refined white flour. Different heating techniques used during processing, and the addition of other ingredients for specific products, create a wide variety of grain-based foods for the food marketplace.

Although minerals are not destroyed by processing procedures, mineral content is decreased when whole grains are milled into refined white flours. When processing losses are significant, mineral contents of flours may be adjusted by enrichment or fortification. Other products commonly enriched include breads, mixes, and other baked foods. Enrichment indicates that selected minerals that were present before processing are added back at appropriate levels to replace the losses resulting from processing. In US, iron is the only enrichment mineral added to replace that lost in processing. Other minerals lost from whole grains during processing are not replaced. Enrichment and fortification standards vary among different countries. Fortification indicates that selected nutrients, which may or may not have been present in the grain before processing, have been added to grain-based foods. Examples of several fortified grain-based foods, some highly fortified, are listed in the ready-to-eat cereal category (*see* **Appendix**: Grain Composition Tables).

Dietary Recommendations for Minerals

Recommended mineral intakes for adult men and women are given in Table 1 for the eight minerals in grain-based foods found in **Appendix**: Grain Composition Tables. Concentrations of minerals in foods are also relatively low, but it is not difficult to meet daily needs by eating a variety of foods from each food group. Recommendations in Table 1 are based on new US dietary reference intakes (DRIs). The new recommended dietary allowances (RDAs) developed as a part of the DRIs are given in the table for most of the minerals. The recommended intake for calcium is expressed as adequate intake (AI), which indicates that the amount covers individual needs but insufficient data prevent setting an RDA level. The recommended minimum requirement given for sodium is representative of the amount that would be consumed if no salt were added and only unprocessed foods were eaten. Units of measurement for grain-based minerals are noted in Table 1 and listed in **Appendix**: Units of Grain Science.

Mineral Composition of Grain-Based Foods

Names/descriptions of selected whole grains and grain-based foods from the wide variety available are classified into product categories (*see* **Appendix**: Grain Composition Tables). The table gives serving sizes and data for contents of minerals, vitamins and other nutrients, and food components. Table data are derived from the food and nutrient database developed and maintained by the Nutrition Coordinating Center, Division of Epidemiology, University of Minnesota, Minneapolis, MN, USA. Food product categories included in the table are listed below:

- grains, flours, and cooked cereals;
- pasta and rice;
- ready-to-eat cereal;
- baby food cereals;
- breads and other related products;
- crackers;
- cookies;
- cakes, pastries, and other desserts;
- granola and cereal bars;
- snacks and chips;
- legumes;
- meat substitutes;
- alcholic beverages; and
- ingredients used in grain products.

Some categories have examples of many different foods, while others have only a few similar foods. The uncooked, cooked, and processed foods in these

categories are discussed here based on their mineral contents per serving. Mineral composition comparisons for foods selected from **Appendix**: Grain Composition Tables are given in this article as examples of how to use and understand the data in the table. **Appendix**: Grain Composition Tables provides food names and data for weight of a serving in grams and mineral contents used in comparisons. Information in **Appendix**: Grain Composition Tables is summarized as below:

- abbreviations explained in table footnotes;
- food names alphabetized in each category;
- contents of minerals and other nutrients and food components given in amount per serving of the food;
- serving sizes specified in common US household units and weight in grams (*see* **Appendix**: Units of Grain Science for measurement abbreviations and equivalents);
- amount of each mineral per serving of each food calculated based on its serving size in grams; and
- nutrients added through commercial enrichment or fortification are shown in bold italics.

Mineral Content Comparisons

Readers can use the following directions to make mineral content comparisons for selected foods using the serving weight and mineral data in **Appendix**: Grain Composition Tables. To compare mineral contents of foods, select foods, and then use contents of each mineral in each food (based on the same serving weight for each food) to classify the foods according to their mineral content. The serving weight must be the same for each food for a valid comparison. Foods within a category and from different categories can be included in a comparison as long as the weight of a serving for each food is the same. In this article, the mineral contents in foods are compared based on those with highest and lowest content.

Grains, Flours, and Cooked Cereals

This category includes selected unprocessed whole and refined grains and their products. Unprocessed whole grains and some processed grains are rarely eaten uncooked, but occasionally may be eaten cooked. Processed cereals in granulated and other forms are usually eaten cooked. Different types of flours used as ingredients in cereal-based foods are eaten cooked in further processed recipe products that have been baked, extruded, or had heat applied by other methods.

Minerals in whole grains – wheat, rye, barley, brown rice Comparisons of mineral contents (*see* **Appendix**: Grain Composition Tables) for 45 g servings of five classes of dry, unprocessed whole wheat: hard red spring, hard red winter, hard white, soft red winter, soft white; and three other dry, unprocessed grains: rye, barley, and brown rice, show differences among the grains.

Mineral contents highest:

- potassium, iron in soft white wheat;
- sodium, magnesium in brown rice;
- calcium in soft white wheat, rye, brown rice;
- phosphorus in soft red winter wheat;
- zinc in rye; and
- copper in hard red winter wheat, soft red winter wheat, rye.

Mineral contents lowest:

- potassium, iron, zinc, copper in brown rice;
- sodium in all wheats;
- calcium in hard red spring wheat; and
- phosphorus, magnesium in barley.

Minerals in whole wheat Comparisons of mineral contents (*see* **Appendix**: Grain Composition Tables) for 45 g servings of the five dry unprocessed whole wheats from above with each other show differences among them. Wheats include: hard red spring, hard red winter, hard white, soft red winter, and soft white.

Mineral contents highest:

- potassium, calcium, iron, zinc in soft white wheat;
- phosphorus in soft red winter wheat; and
- copper, magnesium in hard red winter wheat, soft red winter wheat.

Mineral contents lowest:

- potassium, calcium in hard red spring wheat;
- sodium in all wheats;
- iron in hard red winter wheat, soft red winter wheat;
- phosphorus in hard red winter wheat;
- zinc in soft red winter wheat;
- copper in hard white wheat; and
- magnesium in soft white wheat.

Minerals in whole rye, barley, and brown rice Comparisons of mineral contents (*see* **Appendix**: Grain Composition Tables) for 45 g servings of the three dry, unprocessed grains, rye, barley, and brown rice from above show differences in mineral contents among the grains.

Mineral contents highest:

- potassium in barley;
- sodium, calcium, magnesium in brown rice;

- calcium in rye and brown rice; and
- iron, phosphorus, zinc, copper in rye.

Mineral contents lowest:

- potassium, iron, zinc, copper in brown rice;
- sodium in rye; and
- calcium, phosphorus, magnesium in barley.

Minerals in whole spelt, triticale, wheat Comparisons of mineral contents (*see* **Appendix**: Grain Composition Tables) for 45 g servings of three similar dry, unprocessed whole grains, spelt, an ancient wheat, triticale, a cross between wheat and rye, and hard red spring wheat show differences among the grains.

Mineral contents highest:

- potassium, calcium, copper, magnesium in triticale;
- sodium in triticale and hard red spring wheat; and
- iron, phosphorus, zinc in spelt.

Mineral contents lowest:

- potassium, calcium, magnesium in hard red spring wheat;
- sodium, copper in spelt; and
- iron, phosphorus, zinc in triticale.

Minerals in processed wheat products Comparisons of mineral contents (*see* **Appendix**: Grain Composition Tables) for 45 g servings of whole-wheat flour ground from unprocessed whole-wheat and of white flour, wheat, all purpose, unenriched milled from unprocessed whole wheat show differences from effects of processing.

Mineral contents highest:

- All minerals in whole-wheat flour.

Mineral contents were lowest for all minerals in white unenriched wheat flour.

When the same serving size of enriched white all-purpose wheat flour is added to the comparison above, data for the three flours show the effect of enrichment on iron content.

Mineral contents highest:

- potassium, sodium, calcium, phosphorus, zinc, copper, magnesium in whole-wheat flour; and
- iron in enriched white flour.

Mineral contents were lowest for all minerals in white unenriched flour, and for all minerals, except iron, in enriched white flour.

Minerals in processed rice products Comparisons of mineral contents (*see* **Appendix**: Grain Composition Tables) for 45 g servings of whole-grain brown rice flour and refined white rice flour show differences from effects of processing.

Mineral contents highest:

- Potassium, sodium, iron, phosphorus, zinc, copper, magnesium in brown rice flour.

Concentrations were lowest for minerals listed above in white rice flour, and were the same for calcium in both brown and white rice flours.

Pasta and Rice

This category consists of various types of cooked pasta products made from flours from different grains, and uncooked and cooked rice products.

Minerals in pasta Comparisons of the mineral contents (*see* **Appendix**: Grain Composition Tables) for 140 g servings of macaroni/spaghetti/noodles, whole wheat, cooked and macaroni/spaghetti/noodles, white, cooked show differences between the two pastas.

Mineral contents highest:

- All minerals in macaroni/spaghetti/noodles, whole wheat, cooked.

Mineral contents were lowest for all minerals in macaroni/spaghetti/noodles, white, cooked.

Minerals in uncooked brown and white rice Comparisons of mineral contents (*see* **Appendix**: Grain Composition Tables) for 45 g servings of uncooked brown and white rice show effects of removing bran and germ during processing.

Mineral contents highest:

- All minerals in uncooked brown rice.

Mineral contents were lowest for all minerals in uncooked white rice.

Minerals in cooked brown and white rice Comparisons of mineral contents (*see* **Appendix**: Grain Composition Tables) for 140 g servings of cooked brown and white rice show differences between the two rice products when cooked.

Mineral contents highest:

- Potassium, sodium iron, phosphorus, zinc, copper, magnesium in cooked brown rice.

Mineral contents were lowest for those listed above in cooked white rice. Calcium contents were the same in both cooked brown and white rice.

Ready-to-Eat Cereals

This category is composed of ready-to-eat cereals, each processed primarily from one type of grain (corn, oats, rice, or wheat), with other ingredients added for flavor, texture, and appearance, and fortified with a limited number of minerals. Fortified values are in bold italics in the table (*see* **Appendix**: Grain Composition Tables). None of the cereals are fortified with potassium, sodium, phosphorus, copper or magnesium.

Fortification of ready-to-eat cereals listed:

- Calcium, iron, zinc in unsweetened corn nuggets, puffed corn.
- Iron, zinc in bran flakes without raisins, unsweetened bran nuggets, oat flakes, unsweetened oat rings, wheat and barley nuggets.
- Iron only in unsweetened corn flakes, rice flakes, wheat flakes without raisins.
- Zinc only in wheat and barley flakes.
- No fortification in unsweetened rice nuggets, puffed rice, puffed wheat, unsweetened shredded wheat.

Baby Food Cereals

This category contains three representative baby food cereals in the highly processed dry, instant form. All are fortified with minerals and vitamins to increase nutrient levels (*see* **Appendix**: Grain Composition Tables).

Breads and Other Related Products

This category consists of many kinds of yeast bread, bread rolls, bagels, other assorted bread-based products and quick breads. These foods are made with a variety of flours and added ingredients for color, texture, flavor, and minerals. Effects of added ingredients on mineral contents are variable depending on the food item and amount added. Bread products made from white flour are usually enriched with iron. Enrichment does not include other minerals such as potassium, sodium, calcium, phosphorus, zinc, copper, or magnesium. Whole-wheat bread-based products are not enriched.

Whole-wheat and white pita breads are not enriched, and have the same serving sizes, therefore their mineral contents can be compared.

Minerals in pita bread Comparison of mineral contents (*see* **Appendix**: Grain Composition Tables) for 50 g servings of pita bread from whole-wheat flour and pita bread from unenriched white flour show differences between breads made from the two flours.

Mineral contents highest:

- Potassium, iron, phosphorus, zinc, copper, magnesium in whole-wheat pita bread.
- Sodium, calcium in white pita bread.

Mineral contents were lowest for all minerals except sodium and calcium in white pita bread.

Crackers

This category includes crackers that contain a variety of flours and added ingredients for color, texture, flavor, and minerals. Nearly all products are enriched with iron but not with other minerals. Mineral contents of whole-grain crackers can be compared because they are not enriched.

Minerals in whole-wheat and rye crackers Comparisons of mineral contents (*see* **Appendix**: Grain Composition Tables) for 30 g servings of three unenriched crackers: whole-wheat crackers, cheese-filled sandwich whole-wheat crackers, and rye wafer, plain, show differences from added ingredients and processing among these crackers.

Mineral contents highest:

- Potassium, iron, zinc, copper, magnesium in rye wafer, plain.
- Sodium, calcium, phosphorus in cheese-filled sandwich whole-wheat crackers.

Mineral contents lowest:

- Potassium, sodium, phosphorus in whole-wheat crackers.
- Iron, zinc, copper, magnesium in cheese-filled sandwich whole-wheat crackers.
- Calcium in rye wafer, plain.

Cookies

This category is composed of a variety of commonly consumed cookies (*see* **Appendix**: Grain Composition Tables). Most of them contain similar basic ingredients to which added ingredients provide different flavors, textures, appearance, and minerals. All but one kind of cookie are enriched with iron, but not the other minerals, and one cereal bar is fortified. Effect of minerals contributed by added ingredients is variable depending on food items and amount added.

Cakes, Pastries, and Other Desserts

This category contains a wide variety of popular cakes, desserts, pie crusts and a few complete pies (*see* **Appendix**: Grain Composition Tables). Mineral contents vary depending on kind and amount of added ingredients and weight of a serving. All but

a few foods are enriched with iron, but not the other minerals.

Granola and Cereal Bars

This category consists of two examples of these bars that are representative of those available in retail stores (*see* **Appendix**: Grain Composition Tables). Breakfast bars (intended as a meal replacement) are fortified with calcium, iron, and zinc, but not potassium, sodium, phosphorus, copper, or magnesium. Cereal bars are only fortified with iron, and at a lower level than breakfast bars.

Snacks and Chips

This category contains foods representative of the wide variety of available grain-based snack foods (*see* **Appendix**: Grain Composition Tables). Most snacks and chips are not enriched; none are fortified. Of the items listed, only bagel chips and pretzels are enriched with iron.

Minerals in snacks and chips Comparisons of mineral contents (*see* **Appendix**: Grain Composition Tables) for 30 g servings of the unenriched products show effects of kind of grain used, added ingredients, processing or method of preparation (popped popcorn).

Mineral contents highest:

- potassium, copper, magnesium in hot air popped popcorn;
- calcium, iron in taco or tortilla chips;
- sodium in cheese balls, puffs, or twists;
- zinc, copper in wheat nuts; and
- phosphorus, magnesium in rice cake.

Mineral contents lowest:

- potassium, calcium, phosphorus, zinc, copper, magnesium in corn chips;
- sodium in popcorn popped in hot air; popcorn popped in hot fat;
- iron in rice cake; and
- copper in taco or tortilla chips.

Legumes

This category contains a collection of commonly used legumes. Overall, these cooked legumes are excellent sources of minerals, except sodium.

Minerals in legumes Comparisons of mineral contents (*see* **Appendix**: Grain Composition Tables) for 90 g servings show differences in minerals among cooked legumes.

Mineral contents highest:

- potassium in cowpeas, mung beans, northern beans;
- sodium in fava beans;
- calcium, iron, phosphorus, copper, magnesium in soybeans; and
- zinc in adzuki beans.

Mineral contents lowest:

- potassium, iron, zinc, magnesium in bayo beans;
- sodium in bayo beans, black beans, broadbeans, navy beans, soybeans;
- calcium in pigeonpeas, yellow or green split peas; and
- phosphorus and copper in fava beans.

Meat Substitutes

This category contains examples of soybeans processed into the meat substitutes "miso," "tempeh," and "tofu."

Minerals in meat substitutes Comparisons of mineral contents (*see* **Appendix**: Grain Composition Tables) for 85 g servings of these foods show differences in effects of processing among them.

Mineral contents highest:

- potassium, iron, phosphorus, zinc, copper, magnesium in tempeh;
- sodium in miso; and
- calcium in firm tofu.

Mineral contents lowest:

- potassium, calcium, iron, phosphorus, copper, magnesium in miso;
- zinc in silken tofu; and
- sodium in soft tofu.

Alcoholic Beverages

This category includes beverages fermented from grains. Overall, the beers have variable contents of minerals, but the scotch and whiskey have small serving sizes and very low contents of only iron, phosphorus, zinc.

Minerals in beer Comparisons of mineral contents (*see* **Appendix**: Grain Composition Tables) for 8 fluid ounce servings of the various beers show differences among them.

Mineral contents highest:

- iron, zinc, copper in light, low calorie beer; and
- potassium, sodium, phosphorus, magnesium in regular beer.

Calcium content was highest and did not differ among light, low calorie beer, low alcohol beer, and regular beer.

Mineral contents lowest:

- potassium, in low alcohol beer;
- iron in regular beer;
- phosphorus in low alcohol beer;
- magnesium in light, low calorie beer; and
- zinc, copper – none in low alcohol beer.

Sodium content was lowest and did not differ between light, low calorie beer and low alcohol beer.

Ingredients Used in Grain Products

This category consists of several ingredients commonly added to various grain-based foods during preparation and processing to add variety in color, flavor, texture, and minerals to the grain-based foods. Some are excellent sources of minerals.

Minerals in ingredients used in grain-based foods Comparisons of mineral contents (*see* **Appendix**: Grain Composition Tables) for 30 g servings of these foods show wide differences among them.

Mineral contents highest:

- potassium in low fat peanut flour;
- sodium in dry roasted, salted peanuts;
- calcium, iron in poppy seeds;
- phosphorus, copper in sunflower seeds, dry roasted, salted;
- zinc in sesame seeds, hulled kernels, dried; and
- magnesium in flax seeds.

Mineral contents lowest:

- potassium, phosphorus, iron, zinc, copper, magnesium in arrowroot flour;
- calcium in arrowroot flour, cashews, oil roasted; and
- sodium – none in raw almonds, raw filberts, low fat peanut flour, and raw pecans.

Summary

Grains and grain-based foods are important food sources of minerals. Mineral contents of grains are obtained from minerals in the soil in which they are grown. Minerals have metabolic functions in plants, animals, and humans. The mineral contents of various grains differ from one another. Processing does not destroy minerals, but they can be physically lost from cut surfaces, leached into cooking liquid, or by removing bran and germ that contain most of the minerals in the grain. The addition of ingredients to produce grain-based foods can increase mineral contents. This article presents comparisons of the mineral composition of selected grains and grain-based foods.

Acknowledgments

The author thanks Nancy Van Heel and Sally Schakel, both from the Nutrition Coordinating Center, Division of Epidemiology, University of Minnesota, for developing the food and nutrient data base in **Appendix**: Grain Composition Tables of this encyclopedia, and for their helpful suggestions on this manuscript, and Dr. Joan Gordon, retired faculty member, from the Department of Food Science and Nutrition, University of Minnesota, for her helpful suggestions on this manuscript.

Soy-Based Foods

A M Fehily, Tinuviel Software, Warrington, UK

The soybean (*Glycine max*) is a native of China, where it has been part of the diet for several thousand years. It has also been important in Japan and Korea for almost as long. More recently, soybeans have become widely used in Western countries to produce a diverse range of foodstuffs. This article describes the use of soy in our food supply, the composition of soybeans, the role of soy in the diet, and its potential health benefits.

Use of Soy in Foods

Soybeans are perhaps the most versatile of plants, providing the source for a wide range of ingredients. In the Far East, soybeans are used to produce foods such as "tofu," "miso," "tempeh," and soy sauce. In Western countries, soybeans have become widely used in recent years in the production of a range of very diverse ingredients, e.g., soy flour, soy protein, soy oil, soy lecithin, and mono- and diglycerides of fatty acids. These ingredients are widely used in foods. For example, soy flour and soy protein are used in foods such as breads, pizza bases, other cereal products, and some meat products. Soy protein is often used to make vegetarian alternatives to meat products, e.g., textured vegetable protein (TVP) in vegetarian burgers, vegetarian sausages, etc. Soy oil is used as a vegetable oil both in domestic cooking and by the food industry. Soy oil is also used in the manufacture of spreadable fats. Soy lecithin and mono- and diglycerides of fatty acids are used as emulsifiers in many foods, e.g., breads, fat spreads, and ice cream. Vegan alternatives to cow's milk, cheese, and yogurt are produced from soy. Soy is also used to produce infant formulas for those infants who are intolerant to lactose or cows' milk protein.

Composition

Soybeans contain a wide range of nutrients. They contain some "antinutrients" and also other components, e.g., isoflavones, which may have beneficial effects on health.

Nutrients

Soybeans contain protein, fat, carbohydrate, vitamins, minerals, and fiber.

Protein Soybeans are a good source of protein, containing 14 g per 100 g. This is more than the protein content in most other vegetables and in most other legumes (typically 5–9 g per 100 g), the exception being peanuts which contain 26 g of protein per 100 g. In terms of protein quality, soy contains substantial amounts of most essential amino acids. When compared with a reference protein (egg), soy protein, like other legumes, is deficient in sulfur-containing amino acids (the essential amino acid methionine and the nonessential amino acid cystine) and has a higher content of lysine. Combining legumes with cereals provides a meal with a high protein quality, as cereals have adequate amounts of sulfur-containing amino acids but are deficient in lysine.

Carbohydrate Soybeans contain 5 g of carbohydrate per 100 g. This is lower than that of many other legumes. Of the total carbohydrate content present, 37% is starch, 41% sugars, and 22% oligosaccharides. The sugars present are sucrose, fructose, and glucose.

Fat Soybeans contain 7 g of fat per 100 g. This is more than the fat content in other legumes, most of which are low in fat. The exception to this is peanuts, which contain 46 g of fat per 100 g. The fatty acid composition of soy has a high ratio of unsaturates to saturates. Of the fatty acids, 16% are saturates, 24% are monounsaturates, and 60% are polyunsaturates. The polyunsaturated fatty acids present are the essential fatty acids – linoleic acid ($18{:}2n{-}6$) and α-linolenic acid ($18{:}3n{-}3$).

Minerals Soybeans contain significant amounts of several minerals: calcium, iron, magnesium, potassium, phosphorus, and zinc (see Table 1). One hundred grams of soybeans provides $\sim$12% of the daily reference nutrient intake (RNI) (UK) for calcium, 20% for iron, 23% for magnesium, 15% for potassium, 45% for phosphorus, and 13% for zinc (see Figure 1).

Table 1 Vitamin and mineral composition of soybeans

	Amount per 100 g as consumed
Sodium	1 mg
Potassium	510 mg
Calcium	83 mg
Magnesium	63 mg
Phosphorus	250 mg
Iron	3.0 mg
Copper	0.32 mg
Zinc	0.9 mg
Manganese	0.7 mg
Selenium	5 μg
Iodine	2 μg
Vitamin A (retinol equivalents)	1 μg
Vitamin D	0 μg
Vitamin E	1.13 mg
Thiamin	0.12 mg
Riboflavin	0.09 mg
Niacin equivalents	2.7 mg
Vitamin B_6	0.23 mg
Vitamin B_{12}	0 μg
Folate	54 μg
Pantothenate	0.18 mg
Biotin	25.0 μg
Vitamin C	Trace

Data from Royal Society of Chemistry and Ministry of Agriculture Fisheries and Food (1991) *McCance and Widdowson's The Composition of Foods*, 5th edn. Cambridge, UK: Royal Society of Chemistry. Crown copyright is reproduced with the permission of the Controller of Her Majesty's Stationery Office.

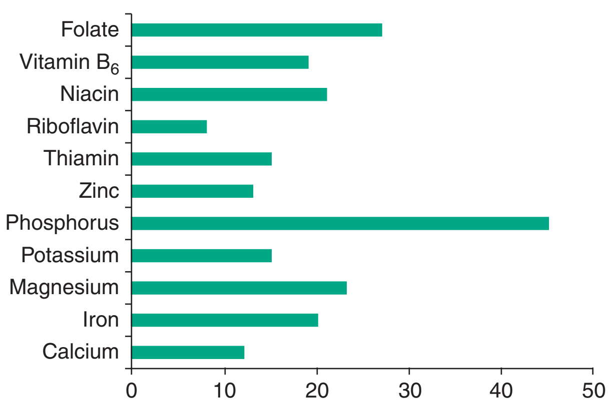

Figure 1 Vitamin and mineral composition of soybeans – in relation to reference nutrient intakes (% of reference nutrient intake (RNI) provided by 100 g). (Reproduced from Encyclopedia of Food Sciences and Nutrition, 2nd Edition (2003), p. 5393, Elsevier Ltd.)

Vitamins Soybeans contain a number of water-soluble vitamins: thiamin, riboflavin, niacin, vitamin B_6, and folate (see Table 1). One hundred grams of soybeans provides ~15% of the daily RNI (UK) for thiamin, 8% for riboflavin, 21% for niacin, 19% for vitamin B_6, and 27% for folate (see Figure 1). Soybeans also contain vitamin E: 1 mg per 100 g.

Fiber Soybeans are a valuable source of fiber in the diet: 6 g of nonstarch polysaccharides (NSP) per 100 g. Of this, 44% is soluble fiber and 56% insoluble fiber. One hundred grams of soybeans provides 33% of the daily "dietary reference value" (UK) for fiber.

Antinutrients

Raw soybeans contain a number of substances which may have detrimental effects on digestion and other metabolic processes (lectins, goitrogens, and digestive enzyme inhibitors). These substances are, however, inactivated by appropriate cooking of the beans or, in the case of goitrogens, counteracted by adequate iodine intake.

Lectins Lectins, also known as haemagglutinins, are present in raw soybeans and in other legumes. They are, however, heat labile and are inactivated when the beans are properly cooked. In experimental animals these polymeric proteins have been shown to cause damage to red blood cells and intestinal mucosa, and thereby impaired nutrient utilization and loss of body weight. In humans, these compounds can result in nausea, vomiting, diarrhoea, and abdominal pain.

Goitrogens Enlargement of the thyroid gland has been shown to occur in rats fed soybean meal. The goitrogenic agent in soybeans is unknown. However, the effect is counteracted by adequate iodine intake.

Digestive enzyme inhibitors Raw soybeans contain certain proteins (protease inhibitors) which react with digestive enzymes (trypsin, chymotrypsin or salivary, and pancreatic α-amylase), thereby interfering with the digestion of protein and starch. In humans, raw soy or isolated protease inhibitors increase levels of cholecystokinin (CCK) and pancreatic secretion. It is thought that chronic pancreatic stimulation may lead to pancreatic hypertrophy, hyperplasia, and possibly to cancer. In rats, raw soy has been shown to increase risk of pancreatic cancer. However, protease inhibitors present in raw soy are inactivated by heat and are therefore not a problem in cooked beans. For example, in countries such as Japan where soy foods are widely consumed, the incidence of pancreatic cancer is similar to or less than that for Western countries where soy forms a relatively small component of the total diet.

Phytic acid Phytic acid is present in soybeans and also in other fiber-containing foods. It has been suggested to reduce the absorption of calcium, iron, zinc, and vitamin D from the diet. However, these effects have been observed in *in vitro* experiments and not in *in vivo* studies, even at fiber intakes at

the upper limit of the normal human consumption range. In addition, levels of micronutrients tend to be higher in fiber-rich foods than in fiber-poor foods. Thus, adverse effects of phytic acid on nutrient absorption are likely to be unimportant at the levels of fiber normally consumed in the human diet.

Isoflavones

Soybeans contain isoflavones, a group of compounds that are structurally similar to oestradiol (phyto-oestrogens). Soybeans contain higher amounts of the isoflavones – genistein and daidzein (see Figure 2) and smaller amounts of glycitein, primarily in the form of glycosides: genistin, daidzin, and glycitin (total isoflavone content of 180 mg per 100 g). The glycosides are hydrolyzed in the gut by a bacterial enzyme, glucose being removed to produce the aglycone forms (genistein, daidzein, and glycitein). Daidzein and genistein have been shown to have weak oestrogenic activity and are able to bind with low affinity to oestrogen receptors, the affinity being greater for β-receptors than for α-receptors. Compared with 17β-oestradiol (the main oestrogen produced by the body), daidzein and genistein have been reported to have much less potency in producing oestrogenic effects, by about 1000-fold or more.

In the 1940s, it was reported that phyto-oestrogens may exert adverse effects on uterine and ovarian function. This was because sheep grazing on pastures, containing a particular type of clover (*Trifolium* sp.) rich in formononetin, which is converted to daidzein in the rumen, developed a widespread infertility. An infertility syndrome has also been described in captive cheetah, as a result of soybean use, the syndrome being reversed by removal of soy from the food. No adverse effects of soybeans on human fertility have been reported.

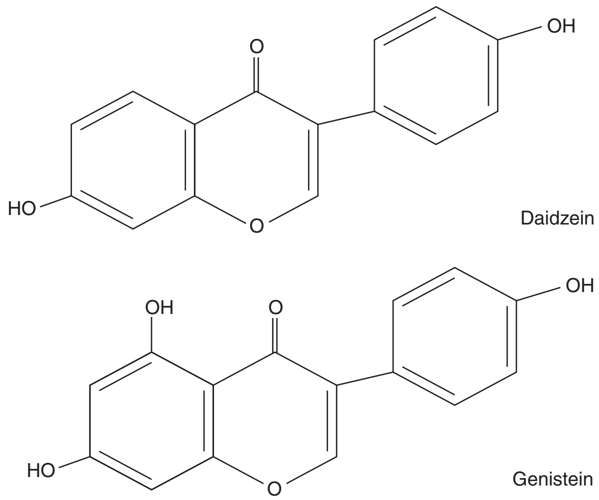

Figure 2 Chemical structure of the main isoflavones present in soy – daidzein and genistein. (Reproduced from Encyclopedia of Food Sciences and Nutrition, 2nd Edition (2003), p. 5394, Elsevier Ltd.)

More recently, it has been recognized that isoflavones may act either as weak oestrogens or as anti-oestrogens, competing for oestradiol at the receptor complex, yet failing to stimulate a full oestrogenic response after binding to the nucleus. This fact has stimulated much research into whether isoflavones may have a protective role in hormone-related diseases such as breast cancer.

Role of Soy in the Diet

Soy has been a staple in the diet of many Far Eastern countries for centuries, e.g., foods such as tofu, tempeh, and miso. These traditional soy foods are not very widely consumed in Western countries, but are sometimes used as an alternative to meat. As soybeans are extremely versatile, as described earlier, consumption of foods containing soy has increased in Western countries over the last 50 years. Nevertheless, the amount of soy consumed in Western countries such as the USA and UK is much less than in countries such as Japan and China. The Food and Agriculture Organisation (FAO) food balance sheets provide data for the amounts of various foods available for human consumption in different countries. These show that the amount of soybeans available for use in foods for humans is 8.5 kg per person per year in China and 7.9 kg per person per year in Japan. This compares with less than 1 kg per person per year in countries such as the USA and UK. In fact, of the soybeans grown worldwide, only ~10% of the total is used in foods for humans, the majority is used as feed for animals.

Soybeans can be an important component of a normal healthy diet as they are low in saturates, provide a source of fiber, and contain a wide range of other nutrients. Soybeans are also the main source of phyto-oestrogens in the diet. In addition, soybeans may have a number of potential health benefits and these are discussed in the following sections.

For vegetarians, and particularly for vegans who eat no animal products, soybeans play a very important role in the diet. They provide a valuable source of protein that can be of high quality if soybeans are combined with cereals, since the amino acid compositions are complementary. They also provide an important source of iron. Low iron intake can lead to iron-deficiency anemia. Ensuring adequate iron status can be difficult for vegetarians as, in general, iron from vegetable sources is less well absorbed than that from animal sources. However, soybeans provide

a source of iron that can be absorbed as well as that in meat.

For infants intolerant to cow's milk protein or to lactose, soy-based infant formulas can be an invaluable alternative to cow's milk-based formulas. For older children and adults who are allergic to cow's milk or intolerant to lactose, drinks and other foods made from soy can be very important components of the diet, helping to ensure that nutrient intakes are adequate for the maintenance of health.

In common with other legumes, soybeans are also of agronomic importance, as they increase the nitrogen content of the soil. Although green plants cannot utilize nitrogen in the atmosphere, there are several species of bacteria, fungi, and blue-green algae that are able to transform nitrogen in the air into a form that can be used by plants. An important genus of nitrogen-fixing bacteria is *Rhizobium*, which forms nodules in the roots of legumes. These bacteria live symbiotically with the legumes, the bacteria obtaining food from the green plant and the legumes obtaining abundant usable nitrogen compounds from the bacteria.

Soy and Coronary Heart Disease

Coronary heart disease (CHD) is a major cause of death in many countries. For example, in the UK, CHD accounts for ~30% of male deaths and 23% of female deaths.

The level of cholesterol in the blood is a major risk factor for CHD. Soy protein substituted for animal protein in the diet results in reductions in total plasma cholesterol (by 9% on average), low-density lipoprotein cholesterol (LDL-C) (by 13% on average), and triacylglycerols (by 11% on average). High-density lipoprotein cholesterol (HDL-C) is unchanged or may be slightly increased. The amount of reduction in blood lipids tends to be greater among those with the highest plasma cholesterol levels at baseline.

A great deal of research has been done to identify the component(s) of soy protein that is responsible for its effect on blood lipids. Studies using a mixture of amino acids that duplicate the amino acid profile of soy protein have found that this does not have the same effect on blood lipids as the intact protein. However, studies of soy protein with isoflavones intact have shown that this has a lipid lowering effect, whereas soy protein with isoflavones removed has no significant effect. It has therefore been suggested that the isoflavones present in soy protein are largely responsible for the lipid lowering effect of soy protein. The benefits of isoflavones present in soy protein on cholesterol lowering have been suggested to be mediated through upregulation of LDL-receptor activity. Nevertheless, studies of isolated and purified isoflavones have failed to show that these have a lipid lowering effect.

Soy may reduce risk of CHD through several mechanisms in addition to its ability to lower blood lipids (see Figure 3). For example, soy isoflavones are known to act as antioxidants and have been suggested to reduce oxidative damage to LDL-C. A decrease in oxidized LDL particles, which are considered atherogenic, may reduce the risk of atherosclerosis.

A study of young cynomolgus monkeys showed that the size of atherosclerotic lesions was 70% less in those fed on a diet containing soy protein with

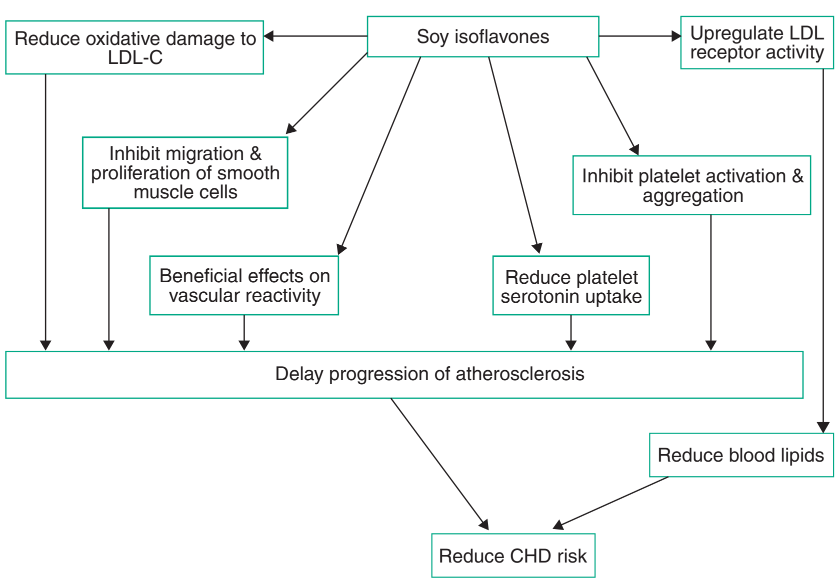

Figure 3 Mechanisms through which soy could reduce risk of coronary heart disease (CHD).

isoflavones present compared with those fed on a diet containing soy protein with isoflavones removed. This suggests that isoflavones may inhibit atherogenesis. In another study of surgically postmenopausal cynomolgus monkeys, soy protein with isoflavones intact was found to reduce the progression of atherosclerosis. The magnitude of the effect was reported to be comparable to that of postmenopausal oestrogen therapy.

Soybean isoflavones, in particular genistein, impact beneficially on vascular reactivity. Genistein has also been shown, *in vitro*, to have a number of other effects whereby the development of atherogenesis may be delayed: inhibition of the migration and proliferation of smooth muscle cells; inhibition of platelet activation and aggregation; and reduction in platelet serotonin uptake.

In 1999, in response to the available evidence on the benefits of soy protein, the USA Food and Drug Administration (FDA) announced that it would allow food manufacturers to label products containing 6.25 g of soy protein per serving as helping to reduce risk of heart disease, as part of a balanced diet low in fat and saturates.

Soy and Cancer

Cancer is a major cause of morbidity and mortality. For example, in the UK about one in three people will develop cancer at some time during their life and cancer accounts for about one in four of all deaths. There are marked differences in death rates from several types of cancer between Asian countries and many Western countries. The differences are more striking for hormone-dependent cancers of the prostate, breast, and colon/rectum. For example, the risk of dying from prostate cancer among Japanese men is only one-fifth that of men in the USA and Japanese women have a breast cancer mortality rate that is only a quarter of that of women in the USA.

Countries where mortality from prostate and breast cancers is low have considerably higher intakes of soy than those countries where mortality from these cancers is high. In animal models, studies investigating the effects of soybeans on prostate cancer or breast cancer have shown reduced tumorigenesis. In humans however, evidence is inconclusive. Epidemiological studies of prostate cancer conducted in Japan and in Japanese migrants to Hawaii have shown no significant effect of soy consumption. However, a recent study in the USA reported that men who drank one cup of soy milk per day had a risk of developing prostate cancer that was 70% lower than that of controls. For breast cancer, although some studies have shown that soy can help prevent breast cancer, others have found no significant effect. An increase in menstrual cycle length has been observed in some studies, in response to soybean consumption, although no change was observed in others. Such an effect is of potential relevance to the hypothesis that soy may be protective against breast cancer, because some data indicate that longer cycles, which are typical of Asian women, are associated with a reduced risk of breast cancer.

For colo-rectal cancer data are also inconclusive: some studies showed no significant effect, some reported a protective effect of soy, and others observed an increased risk with soy consumption. For cancers at other sites, data tend to show that increased soybean consumption may be protective against lung and stomach cancer. Much more research is needed to confirm whether soy has a protective effect against cancer in humans.

Isoflavones appear to be the components of soy that would be most likely to account for any protective action of soy against cancer, especially in inhibiting the initiation stage of carcinogenesis (see Figure 4). Genistein has been shown to suppress the growth of a wide range of cancer cells. It inhibits certain enzymes that could affect the onset of cancer or the growth of tumors: tyrosine protein kinase, mitogen-activated protein (MAP) kinase, and ribosomal S6 kinase. Genistein also inhibits the DNA repair

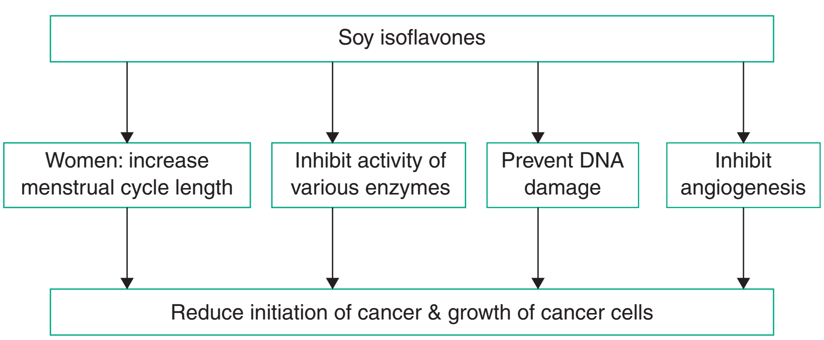

Figure 4 Mechanisms through which soy could reduce risk of cancer.

enzyme topoisomerase II and acts as an antioxidant, thus potentially preventing oxidative DNA damage. It increases *in vitro* concentrations of transforming growth factor β, which is thought to inhibit the growth of cancer cells. In addition, genistein has also been shown to inhibit angiogenesis, the formation of new blood vessels, an abnormal event that occurs as part of the growth and expansion of malignant tumors. However, many of these effects have been shown with very high concentrations of genistein and not in cells treated with levels likely to be achieved in plasma of human subjects eating soy foods.

Soy and Bone Health

Osteoporosis is a clinical condition in which there is a reduced amount of bone per unit volume and an increased susceptibility to fractures, particularly fractures of the vertebrae, distal forearm (Colles fracture) and hip. Of these, hip fracture is the most severe, since patients require a prolonged hospital stay, there is a high mortality rate (about 20% within six months of the fracture) and of those who survive may suffer permanent disability and dependency. Osteoporosis is a major health problem in many Western countries, although not in Asian countries. A number of factors are known to increase risk of osteoporosis, including insufficient dietary calcium, low physical activity, and lack of oestrogen.

In women, bone mass reduces at a rapid rate in the first few years after the menopause, due to the reduction in oestrogen. Hormone replacement therapy (HRT) is well known to reduce bone loss in postmenopausal women. However, HRT is not appropriate for all women. Since soy may have oestrogenic effects, it has been hypothesized that it may provide an alternative to HRT.

Soy protein containing isoflavones has been reported to reduce bone loss due to oestrogen deficiency in ovariectomized rats. Soybean isoflavones have also shown a protective effect on bone loss in ovariectomized rats, suggesting that the beneficial effect of soy protein is due to isoflavones. The effect of isoflavones on bone loss in rats has been reported to be similar to that for oestrogen. The bone sparing effect of soy protein isoflavones has been suggested to be due to a reduction in bone resorption and/or to an increased osteoblast activity (increasing bone formation).

In humans, most but not all studies indicate that soy protein containing isoflavones favorably affects bone turnover and bone mineral density in the lumbar spine of perimenopausal and postmenopausal women. Treatment with ipriflavone, a synthetic isoflavone, has also been reported to have bone conserving effects in postmenopausal women with low bone mass, confirming that the beneficial effect of soy protein is likely to be due to isoflavones.

In addition to the effect of soy protein on bone mineral density, it has also been suggested that soy protein, when substituted for animal protein, may indirectly enhance bone strength. Another effect of soy protein is that it helps to conserve calcium by reducing urinary calcium excretion. This is due to the lower sulfur amino acid content of soy protein.

Soy protein therefore appears to have modest beneficial effects on bone density. However, studies to date have been short term and have involved only small numbers of subjects. In addition, no study has investigated whether soy protein containing isoflavones has an effect on fracture risk.

Soy and Menopausal Symptoms

Hot flushes (also known as hot flashes) are a common symptom among menopausal women in Western societies, but are reported to be much less common in Japan. Whether this difference is due to the higher consumption of soy in Japan is not clear. Hormone replacement therapy (HRT) generally alleviates hot flushes and other menopausal symptoms such as vaginitis. There is much research interest in the possibility that soy may provide an alternative to HRT in this regard.

Evidence of benefit of soy in menopausal women is conflicting. Some researchers have reported an improvement in the frequency of hot flushes in women taking soy protein daily. Others have reported no effect of soy protein on the number of hot flushes experienced but found a reduction in the severity of symptoms. Others have reported a reduction in both the incidence and severity of hot flushes with soy protein or an isoflavone extract compared with a control group. Others have reported no difference in either the frequency or severity of hot flushes in the intervention group compared with the control group.

Two studies have investigated the effects of phytooestrogen supplements on vaginal cytology and found an increase in cell proliferation (an indication of oestrogenic activity) and reversal of menopausal atrophy. Others have reported no significant effect.

There are difficulties in interpreting the results of these studies. This is because there are differences in the amounts of soy protein and isoflavones used and differences in the duration of the studies. Interpretation is also complicated by the fact that reported frequency and severity of symptoms tends to reduce in the control group as well as the intervention group. Thus, much more research needs to be done

before soy protein can be proposed as a potential alternative to HRT for the control of menopausal symptoms.

Vitamin Composition

E Asp, University of Minnesota, South Anoka, MN, USA

Introduction

When grains and grain-based foods are used for humans, they provide essential vitamins and other nutrients for health and wellness. Worldwide, grains are a low-cost staple food in people's food intakes in most cultural groups. Kinds of grains include wheat, corn, rice, oats, barley, rye, and others listed in **Appendix**: Grain Composition Tables. The staple grain used in a culture is determined by the available type, which in turn depends on growing conditions, and, therefore, differs from place to place. Examples of staple grains include: wheat in North America, some parts of Europe, and Australia; corn in Mexico, Central and South America; rice in Asian countries; and rye in northern European countries.

Vitamins are grain components that are synthesized and used by the plants during growth, stored in grain kernels during ripening, and needed during kernel germination for development of new plants. The discovery of the human need for vitamins occurred in Asia in the 1890s when the deficiency disease beriberi caused by eating the staple, polished white rice, was cured and prevented by eating brown rice. Later, the B-vitamin (thiamin) in the outer bran coating of rice kernels was identified as the vitamin that prevented beriberi.

The discovery of specific vitamins began in the early twentieth century. Grains and grain-based foods were identified as important natural sources of six B-vitamins. Research continues today on vitamin synthesis, functions, and storage mechanisms in maturing grain kernels. Study of vitamins includes their functions as biologically active compounds in the human body where they prevent deficiency diseases and decrease risk for chronic diseases. Early dietary studies on vitamins emphasized determining optimal amounts to prevent deficiency diseases and identifying toxic effects of excessive consumption.

As quantitative information about vitamins, minerals, and other nutrients in food became available with improved accuracy of analytical methods and instruments, food composition tables have been developed to present the data. Such a table for vitamins, minerals, and other nutrients and food components in selected grains and grain-based foods are presented in **Appendix**: Grain Composition Tables. Examples of vitamin composition of grains and grain-based foods

have been incorporated from the data provided in **Appendix**: Grain Composition Tables.

Characteristics of Vitamins

Vitamins are "essential organic molecules needed in very small amounts for cellular metabolism." Each vitamin has one or more specific metabolic effects in plants and humans. Of the vitamins in cereals, all are essential for humans except niacin, i.e., they must be provided by food because they cannot be synthesized by the body. Niacin, a B-vitamin, is not classified as essential, because the body can synthesize some of its niacin needs from tryptophan, an amino acid derived from protein. No foods or group of foods provides all essential vitamins, therefore food intakes must include a variety of foods to satisfy human needs for vitamins.

Vitamins are identified by their formal biochemical name, a letter, or a combination of a letter and a number. The names and forms of six B-vitamins and vitamin A found in grains and grain-based foods are listed in Table 1.

Vitamins are classified according to their solubility in water or fat (Table 1). These characteristics affect their processing losses and retention in the body after being eaten. Water-soluble vitamins are not stored in the body. When water is used in processing, preparation, and/or cooking, these vitamins are dissolved out of cut surfaces and leached from other plant tissue. Fat-soluble vitamins are stored in the body if intake exceeds daily needs. Toxicity seldom occurs from food intakes, but is possible if large supplemental doses are routinely ingested.

Stability of vitamins to heat, light, and air affects losses from foods during processing and/or cooking (Table 1). B-vitamins except niacin in grain-based foods are affected by applying heat, e.g., cooking in hot liquid, baking, and extrusion cooking. Riboflavin, pyridoxine (B_6), folate, and vitamin A losses occur when foods are exposed to light. Thiamin, folate, and vitamin A levels are reduced by exposure of food to air. When food-processing losses from heat,

Table 1 Characteristics of vitamins in grains and grain-based foods[a]

Vitamin name	*Major metabolic functions*	*Solubility*	*Stable to*			*US recommended dietary allowances (RDA)[b] or adequate intake (AI)[c]*	
			Heat	*Light*	*Air*	*Men*	*Women*
Thiamin (B_1)	Energy release Neuromuscular function	Water	No	Yes	No	1.2 mg[b,d]	1.1 mg
Riboflavin (B_2)	Energy release Healthy skin, mouth Healthy tongue	Water	No	No	Yes	1.3 mg[b,d]	1.1 mg
Niacin (B_3) Nicotinic acid Niacinamide	Energy release Neuromuscular function Maintain skin	Water	Yes	Yes	Yes	16 mg[b,d]	14 mg
Pyridoxine (B_6) Pyridoxamine Pyridoxal	Energy release Blood formation Neuromuscular function Maintain skin	Water	No	No	Yes	1.3 mg[b,d]	1.3 mg
Folate, folic acid Folacin Pteroyl-glutamic acid	Blood formation Prevent neural tube defects DNA synthesis	Water	No	No	No	400 μg[b,e]	400 μg
Pantothenic acid (B_5)	Energy release Neuromuscular function Fat synthesis	Water	No	Yes	Yes	5.0 mg AI[c,d]	5.0 mg AI
Vitamin A Precursor: carotenoids preformed retinol	Eye function, vision Antioxidant	Fat	No	No	No	900 RE[f]	700 RE

[b] Recommended dietary allowances.
[c] AI = adequate intake.
[d] mg = milligram.
[e] μg = microgram.
[f] RE = retinol equivalent.

light, and air are significant, foods may be enriched or fortified to increase the vitamins that are lost.

Vitamins in grain-based foods, Table 1, have an important role in major metabolic functions. Prevention of deficiency diseases is an important resulting health benefit. These diseases include beriberi linked to thiamin deficiency, pellagra caused by niacin deficiency, xerophthalmia – night blindness and keratomalacia leading to complete blindness resulting from vitamin A deficiency. Neural tube birth defects, i.e., spina bifida, the most common birth defect in the US and other countries, and possibly oral clefts and congenital heart defects, have been linked to folic acid deficiency based on research in recent years. More research on folic acid benefits is needed. Overall, vitamin deficiencies are less prevalent now, but can be found in populations where food is scarce, or illnesses, or addictions cause poor diets. Nutrients added to the diet from increased use of cereals and cereal-based foods can help reduce these deficiencies.

Recommended intakes in the US for six B-vitamins and vitamin A for adults are very small. Concentrations of these vitamins in food are also very small, but it is not difficult to meet daily needs by eating a variety of foods. The recommended intakes for individuals, vitamins in the US, Table 1, are expressed as recommended dietary allowances (RDAs) based on new US dietary reference intakes (DRIs). The recommended intake for pantothenic acid is expressed as adequate intake (AI), which indicates the amount covers individual needs, but lack of data prevents setting an RDA level. Recommendations for vitamin A are given in retinol equivalents (RE). Units of measurement for grain-based vitamins are footnoted in **Table 1**, in **Appendix**: Grain Composition Tables, and listed in **Appendix**: Units of Grain Science.

Grain Kernel Structure and Location of Vitamins

Grain kernels have three major components: bran, germ, and endosperm (*see* **Grain, Morphology of Internal Structure. Grain and Plants, Morphology**). Kernels are covered by several layers of bran. The aleurone layer of bran is next to the endosperm. The largest portion of the kernel is the starchy endosperm. The germ or embryo is the source of the new plant in a germinating kernel. All grains are similar in the types of tissues they contain and in the molecular and cellular organization of their tissues.

Vitamins and other biologically active constituents of grains are synthesized and stored in specific structural locations in the kernel, where they activate a variety of reactions and interactions. The extractability of these constituents from storage within grains varies.

Bran and germ aleurone cells contain most of the important nutrients and other bioactive components in the grain, and are where metabolic activities take place. These cells contain the maximum amount of thiamin, riboflavin, niacin, and pantothenic acid in the kernel. Niacin in the aleurone cells is complexed with protein or carbohydrate making these vitamin deposits difficult to separate from the cells during processing and digestion. It is not known whether thiamin and riboflavin in aleurone cells occur in the niacin complexes. Variable amounts of B-vitamins also are stored in the germ, from which a new plant originates, and in some parts of the starchy endosperm.

Grain-Processing Effects on Vitamins

Grains are unique because they are seldom eaten in the raw state. For optimum benefits from their constituents, grains are processed to produce ingredients for nutritious and palatable grain-based foods. Commercial processing disrupts the organization of the kernels to release vitamins and other constituents from storage in the aleurone cells and elsewhere, and to make the endosperm starch available for digestion. Effects of processing differ for each process and grain combination. Processing techniques include grinding or crushing the entire kernel of the grains into whole grain flours or meals that have minimal vitamin losses, or milling to separate bran, germ, and endosperm of the kernel to obtain refined white flour with significant vitamin losses. Different heating techniques used during processing affect vitamin losses, and the addition of other ingredients for specific products can contribute to the vitamin content and also provide a wide variety of grain-based foods for the food marketplace.

When significant losses occur during processing, nutrient levels in grain-based foods are increased by enrichment or fortification. Products commonly enriched in the US include refined flours, breads, mixes, and other baked foods. "Enriched" indicates that selected nutrients present in grain-based foods before processing or refining are added back to replace nutrient losses resulting from processing. Nutrients added in the US through enrichment are thiamin, riboflavin, niacin, folate, and iron. Enrichment and fortification standards vary among different countries. "Fortified" indicates that specified nutrients are added to grain-based foods that may or may not have been present in the grain before processing. Vitamin A, for example, is added to fortify

grain-based foods that originally contain little or no vitamin A, e.g., ready-to-eat breakfast cereals, making them important grain food sources of vitamin A (*see* **Appendix**: Grain Composition Tables). Vitamin A content of grain-based foods is also increased without fortification, when ingredients high in vitamin A or its precursors are added, such as pumpkin or carrots.

Beginning in 1998, the US Food and Drug Administration required manufacturers of cereal grain products (breads, flours, corn meals, rice, pastas, breakfast cereals, and other grain products) to enrich/fortify them with 140 μg per 100 g of folic acid, the most bioavailable form of the vitamin. These enriched/fortified products are permitted to claim on the label that adequate intake of folic acid may reduce the risk of neural tube-birth defects. Most of these cereals and cereal products already contain some naturally occurring folate, the less bioavailable form of the vitamin that must be digested to yield folic acid. Also, some imported foods, may not meet the US enrichment/fortification standards for folic acid or folate content, or may not be enriched/fortified at all.

Vitamin Composition of Grain-Based Foods

Names/descriptions of selected whole grains and grain-based foods are classified into product categories in **Appendix**: Grain Composition Tables. The table gives serving sizes and data for vitamins, minerals, and other nutrients and food components. Table data are derived from the food and nutrient database developed and maintained by the Nutrition Coordinating Center, Division of Epidemiology, University of Minnesota, Minneapolis, MN, USA. Food product categories included in the table are listed below. Some categories have examples of many different foods, while others have only a few similar foods.

- grains, flours, and cooked cereals;
- pasta and rice;
- ready-to-eat cereal;
- baby food cereals;
- breads and other related products;
- crackers;
- cookies;
- cakes, pastries, and other desserts;
- granola and cereal bars;
- snacks and chips;
- legumes;
- meat substitutes;
- alcoholic beverages; and
- ingredients used in grain products.

Vitamin composition comparisons for foods selected from **Appendix**: Grain Composition Tables are given in this article as examples of how to use and understand the data in the table. The table also gives food names and data for weight of a serving in grams and vitamin contents used in comparisons.

Information in **Appendix**: Grain Composition Tables includes:

- abbreviations explained in table footnotes;
- food names alphabetized in each category;
- contents of vitamins and other nutrients and food components given in amount per serving of the food;
- serving sizes specified in common US household units and weight in grams (*see* **Appendix**: Units of Grain Science for measurement abbreviations and equivalents);
- amount of each vitamin per serving of each food, calculated based on its serving size in grams; and
- nutrients added through commercial enrichment or fortification in bold italics.

Vitamin Content Comparisons

Readers can use the following directions to make their own vitamin content comparisons for selected foods using the serving weight and vitamin data in **Appendix**: Grain Composition Tables. To compare and classify foods on the basis of their vitamin contents, select foods and then use contents of each vitamin in each food (based on the same serving weight for each food). For a valid comparison, the serving weight must be the same for each food. Foods within a category and from different categories can be included in a comparison as long as the weight of a serving for each food is the same.

Information is presented in Table 2, which gives the highest amount of each vitamin that can be expected on the basis of how it is consumed, e.g., cooked, in an unenriched and enriched/fortified grain food, and in another food source highest in a given vitamin. This table enables readers to compare vitamin contents of grain foods relative to the values for other grains and for nongrain food sources.

Grains, Flours, and Cooked Cereals

This category includes selected unprocessed whole grains, and processed whole and refined grain-based foods, in uncooked and cooked forms. Unprocessed whole grains and some processed grains are rarely eaten uncooked, but are sometimes eaten cooked. Processed cereals in granulated and other forms are usually eaten cooked. Different types of

Table 2 Highest vitamin contents per serving for foods, as eaten basis[a]

Vitamin name	*Unenriched grain foods*	*Enriched/fortified grain foods*	*Other food sources of the vitamin*
Thiamin (B_1)	0.281 mg[b] Oatmeal, regular, cooked	0.527 mg Rice flakes, ready-to-eat cereal	0.54 mg Pork chop, fresh, loin, lean, cooked
Riboflavin (B_2)	0.154 mg[b] Quinoa, cooked	0.589 mg Rice flakes, ready-to-eat cereal	0.40 mg Milk, fluid, 2% fat
Niacin (B_3)	3.340 mg[b] Cracked wheat, cooked	7.130 mg Rice flakes, ready-to-eat cereal	4.55 mg Pork chop, fresh, loin, lean, cooked
Pyridoxine (B_6)	0.515 mg[b] Oatmeal, instant cooking, flavored or plain, cooked	2.030 mg Bran flakes without raisins, ready-to-eat cereal	0.34 mg Pork chop, fresh, loin, lean, cooked
Folate	38 μg[c] Millet, cooked	404 μg Bran nuggets, unsweetened, ready-to-eat cereal	179 μg Lentils, cooked 97 μg Spinach, cooked 44 μg Broccoli, cooked
Pantothenic acid (B_5)	0.920 mg[b] Corn flakes, unsweetened, ready-to-eat cereal	Foods are not usually enriched or fortified with this vitamin	Many foods contain this vitamin
Vitamin A	8 RE[d] Cornmeal, cooked	381 RE Oatmeal, instant cooking, flavored or plain, cooked	1900 RE Sweet potato, boiled, mashed 1596 RE Carrots, boiled, drained

[a] Values from **Appendix**: Composition Tables for unenriched and enriched/fortified foods, and from Version 4 of the Nutrition Coordinating Center Nutrient Data Base for other food sources of the vitamins.
[b] mg = milligram.
[c] μg = microgram.
[d] RE = retinol equivalent.

grains and flours are combined with other foods as ingredients in cereal-based foods that are eaten after being cooked by baking, extrusion, or other methods of applying heat. In these foods, grains are the base ingredient and other ingredients add nutrients, flavor, and color, and/or are needed for structure of the food.

The following first comparison of vitamin contents in unprocessed whole grains shows how the food and nutrient data in **Appendix**: Grain Composition Tables can be used to obtain the amounts of vitamins in these products. The range of vitamin contents among the grains (shown numerically as an example of the data for each vitamin and each product) gives the highest and lowest contents, and also provides an indication of how much these foods differ from one another in vitamin content. This information can be obtained from **Appendix**: Grain Composition Tables for the vitamin content of each food for every comparison presented in this article.

Vitamins in whole grains – wheat, rye, barley, brown rice Comparisons of vitamin contents, in **Appendix**: Grain Composition Tables, for 45 g servings of five classes of dry, unprocessed whole wheat: hard red spring, hard red winter, hard white, soft red winter, soft white, and three other dry, unprocessed grains: rye, barley, and brown rice, show differences among the grains.

Vitamin contents highest:

- thiamin (0.227 mg), niacin (2.569 mg) in hard red spring wheat;
- riboflavin (0.113 mg), folate (27 μg), pantothenic acid (0.657 mg) in rye; and
- vitamin B_6 (0.196 mg) in brown rice.

Vitamin contents lowest:

- thiamin (0.086 mg), pantothenic acid (0.126 mg), vitamin B_6 (0.117 mg) in barley;
- riboflavin (0.028 mg), folate (6 μg) in brown rice;
- niacin (1.921 mg) in rye; and
- vitamin A (5 IU (International Units)) in rye. None in the other grains.

Vitamins in whole wheat Comparisons of vitamin contents, in **Appendix**: Grain Composition Tables, for 45 g servings of the five dry unprocessed whole wheat listed above, with each other show differences.

Vitamin contents highest:

- thiamin, niacin, folate in hard red spring wheat;
- riboflavin in hard red winter wheat;
- pantothenic acid the same in hard red winter wheat and hard white wheat; and
- vitamin B_6 in soft white wheat.

Vitamin contents lowest:

- thiamin in hard red winter wheat;
- riboflavin, pantothenic acid, vitamin B_6 in soft red winter wheat;
- folate the same in hard red winter wheat and hard white wheat;
- niacin in hard white wheat;
- pantothenic acid in soft white wheat; and
- vitamin A – none in these wheat.

Vitamins in whole rye, barley, brown rice Comparisons of vitamin contents, in **Appendix**: Grain Composition Tables, for 45 g servings of the three dry, unprocessed grains, rye, barley, and brown rice from above show differences in vitamin contents among the grains.

Vitamin contents highest:

- thiamin, niacin, vitamin B_6 in brown rice;
- riboflavin, folate, pantothenic acid in rye; and
- vitamin A in rye.

Vitamin contents lowest:

- thiamin, riboflavin, pantothenic acid, vitamin B_6 in barley;
- niacin in rye;
- folate in brown rice; and
- vitamin A – none in barley or brown rice.

Vitamins in whole spelt, triticale, wheat Comparisons of vitamin contents, in **Appendix**: Grain Composition Tables, for 45 g servings of three similar dry, unprocessed whole grains, spelt, a predecessor of wheat, triticale, a cross between wheat and rye, and hard red spring wheat show differences among the grains.

Vitamin contents highest:

- thiamin in hard red spring wheat;
- riboflavin, niacin in spelt;
- folate, pantothenic acid, vitamin B_6 in triticale; and
- vitamin A in spelt and triticale.

Vitamin contents lowest:

- thiamin in spelt;
- riboflavin, folate, pantothenic acid, vitamin B_6 in hard red spring wheat;
- niacin in triticale; and
- vitamin A – none in hard red spring wheat.

Vitamins in processed wheat products Comparisons of vitamin contents, in **Appendix**: Grain Composition Tables, for 45 g servings of whole wheat flour ground from unprocessed whole wheat and of white flour, wheat, all-purpose, unenriched milled from unprocessed whole wheat show differences from effects of processing.

Vitamin contents highest:

- All vitamins in whole wheat flour.

Vitamin contents were lowest for all vitamins in white unenriched flour.

When 45 g servings of white flour, wheat, all-purpose, enriched are added to the comparison, data for the three flours show vitamin contents are not always highest with enrichment. Flour enrichment includes thiamin, riboflavin, niacin, folate, iron, but not pantothenic acid, vitamin B_6 or Vitamin A.

Vitamin contents highest:

- thiamin, riboflavin, folate in white flour, wheat, all-purpose, enriched; and
- niacin, pantothenic acid, vitamin B_6, vitamin A in whole wheat flour.

Vitamin contents lowest:

- thiamin, riboflavin, niacin, folate in white flour, wheat, all purpose, unenriched.

Vitamin contents of pantothenic acid, vitamin B_6, and vitamin A in unenriched and enriched white flours are the same or similar because enrichment does not include these vitamins.

Vitamins in processed rice products Comparison of vitamin contents, in **Appendix**: Grain Composition Tables, for 45 g servings of whole grain brown rice flour and refined white rice flour show differences from effects of processing.

Vitamin contents highest:

- All B-vitamins in whole grain brown rice flour.

Vitamin contents were lowest for all B-vitamins, and vitamin A is not found in either whole grain brown rice flour or in refined white rice flour.

Pasta and Rice

This category consists of various types of cooked pasta products made from flours from different grains, and uncooked and cooked rice products.

Vitamins in pasta Comparisons of vitamin contents, in **Appendix**: Grain Composition Tables, for 140 g servings of macaroni/spaghetti/noodles, whole wheat, cooked and macaroni/spaghetti/noodles, white, cooked show differences between the two pastas.

Vitamin contents highest:

- thiamin, riboflavin, niacin, pantothenic acid, vitamin B_6 in whole wheat, cooked pasta; and
- folate and vitamin A in white, cooked pasta.

Vitamin contents were lowest for thiamin, riboflavin, niacin, pantothenic acid, vitamin B_6 in white cooked pasta. However, folate and vitamin A were lowest in whole wheat cooked pasta.

Vitamins in uncooked brown and white rice Comparisons of vitamin contents, in **Appendix**: Grain Composition Tables, for 45 g servings of uncooked brown and white rice show effects of removing bran and germ during processing.

Vitamin contents highest:

- thiamin, riboflavin, niacin, folate, vitamin B_6 in uncooked brown rice; and
- pantothenic acid in uncooked white rice.

Vitamin contents were lowest for thiamin, riboflavin, niacin, folate, vitamin B_6 in uncooked white rice. Pantothenic acid was lowest in uncooked brown rice, and no vitamin A was found in either uncooked brown or white rice.

Vitamins in cooked brown and white rice Comparisons of vitamin contents, in **Appendix**: Grain Composition Tables, for 140 g servings of cooked brown and white rice show effects of water solubility and heat sensitivity of the vitamins in the two types of rice during cooking.

- The same vitamins were highest and lowest for cooked brown and white rice as for uncooked brown and white rice in the comparisons above.

Cereal, Ready-to-Eat

This category is composed of ready-to-eat cereals, each processed primarily from one type of grain (corn, oats, rice, wheat), with other ingredients added for flavor, texture, and vitamins and by fortifying most of the cereals listed with vitamins except pantothenic acid (*see* **Appendix**: Grain Composition Tables). Cereals fortified with vitamin A makes them important sources of the vitamin, with several cereals at higher levels of added vitamin A than the RDAs for men and women (Table 1). Highest levels of folate in the fortified cereals are at or above the RDA level, 400 μg per serving (Table 1). Fortification levels for rice flakes make this food highest in contents for thiamin, riboflavin, and niacin, one of the four cereals highest in folate, and third highest in vitamin A.

Baby Food Cereals

This category contains three representative baby food cereals in the highly processed dry, instant form. All are fortified with vitamins and minerals to increase nutrient levels (*see* **Appendix**: Grain Composition Tables).

Breads and Other Related Products

This category consists of many kinds of yeast bread, bread rolls, bagels, other assorted bread-based products and quick breads. Nearly all these foods are enriched with thiamin, riboflavin, niacin, folate, and iron, but not with pantothenic acid and vitamin B_6 (*see* **Appendix**: Grain Composition Tables). Most of these products contain little or no vitamin A. Higher vitamin A levels in some products are from added ingredients such as eggs and/or milk. Whole wheat products, taco shell, corn tortilla, and white pita bread are not enriched.

Vitamins in pita bread Comparisons of vitamin contents, in **Appendix**: Grain Composition Tables, for 50 g servings of pita bread from whole wheat flour and pita bread from unenriched white flour show differences between breads made from the two flours.

Vitamin contents highest:

- thiamin, niacin, folate, pantothenic acid, vitamin B_6, vitamin A in whole wheat flour pita bread; and
- riboflavin in white flour pita bread.

Vitamin contents were lowest for thiamin, niacin, folate, pantothenic acid, vitamin B_6, and no vitamin A was found in white flour pita bread. Riboflavin was lowest in whole wheat flour pita bread.

Crackers

This category includes crackers that contain a variety of flours and added ingredients for color, texture, flavor, and vitamins. Nearly all products are enriched with thiamin, riboflavin, niacin, folate, and iron but not pantothenic acid and vitamin B_6.

Vitamins in whole wheat and rye crackers Comparisons of vitamin contents, in **Appendix**: Grain Composition Tables, for 30 g servings of three unenriched crackers: whole wheat crackers, cheese-filled sandwich whole wheat crackers, and rye wafer, plain, show differences from added ingredients and processing among these crackers.

Vitamin contents highest:

- thiamin, vitamin B_6 in rye wafer, plain;
- riboflavin, folate, vitamin A in cheese-filled sandwich whole wheat crackers; and
- niacin, pantothenic acid in whole wheat crackers.

Vitamin contents lowest:

- thiamin, riboflavin, folate, vitamin B_6 in whole wheat crackers;

- niacin, pantothenic acid in rye wafers, plain; and
- vitamin A – none in rye wafers, plain, and whole wheat crackers.

Cookies

This category is composed of a variety of commonly consumed cookies. Most of them contain similar basic ingredients to which added ingredients provide flavors, textures, appearance, and vitamins. All but one kind of cookie are enriched with thiamin, riboflavin, niacin, folate and iron, but not pantothenic acid, vitamin B_6 or vitamin A, and one cereal bar is fortified (*see* **Appendix**: Grain Composition Tables). Vitamin A contributed by added ingredients increased vitamin A content in nearly all cookies listed.

Cakes, Pastries, and Other Desserts

This category contains a wide variety of popular cakes, desserts, piecrusts and a few complete pies. All foods are enriched with thiamin, riboflavin, niacin, folate, and iron, but not pantothenic acid and vitamin B_6 (*see* **Appendix**: Grain Composition Tables). Vitamin A content is high in some foods listed, and low or none in others, depending on vitamin A in added ingredients. Carrots in carrot cake and pumpkin in pumpkin pie greatly increased vitamin A contents in these foods.

Granola and Cereal Bars

This category consists of two examples of these bars that are representative of those available in retail stores. Breakfast bars are fortified at higher levels than cereal bars with thiamin, riboflavin, niacin, folate, vitamin B_6, and vitamin A, but no pantothenic acid is added, (*see* **Appendix**: Grain Composition Tables).

Snacks and Chips

This category contains foods representative of the wide variety of available grain-based snack foods. Most snacks and chips are not enriched, and none listed are fortified (*see* **Appendix**: Grain Composition Tables). Of the items listed, only bagel chips and both kinds of pretzels are enriched with thiamin, riboflavin, niacin, folate, but not pantothenic acid or vitamin B_6 or vitamin A.

Vitamins in snacks and chips Comparisons of vitamin contents, in **Appendix**: Grain Composition Tables, for 30 g servings of the unenriched products show effects of kind of grain used, added ingredients, processing, and cooking (popcorn).

Vitamin contents highest:

- thiamin, riboflavin, vitamin A in taco or tortilla chips;
- niacin, pantothenic acid in rice cake; and
- folate, vitamin B_6 in wheat nuts.

Vitamin contents lowest:

- thiamin, riboflavin, folate in corn nuts;
- niacin in microwave popped popcorn;
- pantothenic acid in corn chips;
- vitamin B_6 in microwave popped popcorn; popcorn popped in fat; rice cake; and
- vitamin A – none in rice cake or pretzels.

Legumes

This category contains a collection of commonly used legumes. Overall, these cooked legumes are excellent sources of the B-vitamins, but not vitamin A.

Vitamins in legumes Comparisons of vitamin contents (*see* in **Appendix**: Grain Composition Tables) for 90 g servings of these cooked foods show differences among legumes.

Vitamin contents highest:

- thiamin in black beans, broadbeans, cowpeas, navy beans;
- riboflavin, vitamin B_6 in soybeans;
- niacin, vitamin A in fava beans; and
- folate, pantothenic acid in lentils.

Vitamin contents lowest:

- thiamin in tepary beans;
- riboflavin, folate in bayo beans;
- niacin in brown beans, mung beans, northern beans;
- pantothenic acid in fava beans;
- vitamin B_6 in pigeonpeas, yellow or green split peas; and
- vitamin A – none in several types of legumes.

Meat Substitutes

This category contains examples of soybeans processed into the meat substitutes "miso," "tempeh," and "tofu."

Vitamins in meat substitutes Comparisons of vitamin contents, in **Appendix**: Grain Composition Tables, for 85 g servings of these foods show differences in effects of processing among them.

Vitamin contents highest:

- thiamin in silken tofu;
- riboflavin, pantothenic acid, vitamin B_6, vitamin A in tempeh; and
- niacin, folate in firm tofu.

Vitamin contents lowest:

- thiamin, vitamin B_6 in extra firm tofu;
- riboflavin in extra firm tofu, silken tofu, soft tofu;
- niacin in silken tofu;
- folate in tempeh;
- pantothenic acid in silken tofu, soft tofu; and
- vitamin A – none in firm tofu, silken tofu, soft tofu.

Alcoholic Beverages

This category includes beverages fermented from grains. Overall, the 8 fluid ounce servings of beers contain B-vitamins, but 1.5 fluid ounce servings of scotch and whiskey contain practically none.

Vitamins in beer Comparisons of vitamin B contents, in **Appendix**: Grain Composition Tables, for 8 fluid ounce servings of the various beers show differences among them.

Vitamin contents highest:

- thiamin, riboflavin in light, low calorie beer;
- thiamin, riboflavin, niacin, folate in regular beer;
- pantothenic acid in low alcohol beer; and
- vitamin B_6 in regular beer, low alcohol beer.

Vitamin contents lowest:

- thiamin, riboflavin, niacin, folate in low alcohol beer;
- pantothenic acid and vitamin B_6 in light, low calorie beer; and
- vitamin A – none in alcoholic beverages.

Ingredients Used in Grain Products

This category consists of several ingredients commonly added to various grain-based foods during preparation and processing to add color, flavor, texture, and vitamins. Some are excellent sources of B-vitamins.

Vitamins in ingredients used in grain-based foods Comparisons of vitamin contents, in **Appendix**: Grain Composition Tables, for 30 g servings of these foods show wide differences among them.

Vitamin contents highest:

- thiamin in raw sunflower seeds;
- riboflavin raw almonds;
- niacin and folate in defatted peanut flour;
- pantothenic acid in dry roasted, salted sunflower seeds;
- vitamin B_6 in flax seeds; and
- vitamin A in arrowroot flour.

Vitamin contents were lowest in arrowroot flour for all vitamins except vitamin A. Vitamin A was not found in several ingredients.

Summary

Grains and grain-based foods are important food sources of B-vitamins, but not vitamin A unless fortified, or contain added ingredients high in vitamin A content. B-vitamins, which are synthesized in grain plants and stored in the kernels, have metabolic functions in the plant and in the human body when eaten by people. Different grains differ from one another in vitamin composition. Changes in vitamin composition occur during processing.

O

OATS

P K Zwer, SARDI, Adelaide, SA, Australia

Introduction

Oats have played a significant role in farming systems from domestication to present due to the versatile uses of the grain and plant (Figure 1). Oats currently rank sixth in world production of cereals after maize, rice, wheat, barley, and sorghum. World oat production was similar to millet and exceeded rye, and triticale.

Oats are primarily grown in cool temperate climates with ~67% of world production occurring in the northern hemisphere. The Russian Federation, Canada, United States of America, Finland, and Poland were ranked as the top five countries for world oat production. Oats are also grown in the southern hemisphere with Australia ranked first in production while Argentina, Chile, and Brazil are also significant producers.

There are two types of oats – husked oats, with hulls surrounding the kernel or groat after harvest and naked oats, where the hull is removed when the crop is harvested. Naked oats have the free threshing character similar to wheat. Husked oats represent the majority of oat production, but naked oats are gaining prominence for specialist markets as improved varieties are being developed.

Oats are used for animal feed, human consumption, and nonfood uses. Figure 2 shows the uses of oats relative to the proportions utilized.

Oats were a traditional feed on farms for centuries and powered workhorses until the introduction of

Figure 1 Oat plants pictured at heading.

Figure 2 The main end uses of oats are shown with the largest proportion used for animal feed, the second major use for human consumption, and minor uses for industrial, cosmetic, and pharmaceuticals.

machinery powered by fossil fuels. Between 50% and 90% of the world oat production is used as animal feed for horses, cattle, and sheep. Naked oats are particularly suited for poultry, pigs, racehorses, and birds. Oats as an animal fodder are also important for domestic and export markets. Oats can be grazed as a green feed, made into silage, utilized as straw, or baled for hay.

Oats for human consumption are used to produce traditional, functional, and medicinal products. Oats are differentiated from other cereal grains by using the entire kernel after the hull is removed for many food products. Porridge or oatmeal, hot cereals, bread, biscuits, infant food, and muesli or granola bars are a few examples of food products produced from oats. Nondairy food uses have been developed resulting in oat milk, yogurt, and ice cream. Oats have been shown to have health benefits for lowering blood cholesterol, normalizing blood glucose levels, and reducing the risk of colorectal cancer. Although pharmacological properties are reported in the literature, no products have been commercialized.

Nonfood and industrial oat products vary from cosmetics to the production of cardboard products to the manufacture of furfural and furnan compounds used for solvents, adhesives, filtering aids, and the construction of board material and cellulose pulp.

Although oat production is declining globally, specialization for animal feed, hay, food, industrial, and pharmaceutical products is growing and provides opportunities for adding value to the oat crop.

This article will briefly outline the significance of oats as a cereal crop including origin, domestication, plant morphology, production, end uses, and variety improvement.

Classification

The genus of oat is *Avena* L.(Poaceae) and belongs to the tribe Aveneae of the family Gramineae. The primary species cultivated is *Avena sativa*. However, *Avena byzantina* and *Avena strigosa* are also grown in some regions for animal feed and fodder.

The species described in *Avena* form a polyploid series varying from one to three chromosome sets with the basic chromosome number (n) seven. Each chromosome set has a genome designation A, B, C, D donated by a different oat species in the evolution of the genus. The different species with varying ploidy levels evolved over time and will be discussed below. The diploid species have one set of chromosomes and are designated as $2n = 2x = 14$. This designation indicates the diploid is composed of one genome with 14 chromosomes. The tetraploid species have two sets of chromosomes and are designated $2n = 4x = 28$. This designation indicates the tetraploid has two different genomes each with 14 chromosomes to total 28. The hexaploid species include cultivated oats and have three sets of chromosomes designated $2n = 6x = 42$. This designation shows that the hexaploid species are composed of three genomes each with 14 chromosomes to total 42 chromosomes.

History of Oats

Speciation

Three distinct diploid genomes A, C, and D hybridized in the development of cultivated oats. Each genome was composed of 14 chromosomes. The specific species that hybridized to form cultivated oats has been difficult to ascertain. Several species have been described with the A and C genomes, but no species have been identified with the D genome. Nonetheless, domesticated oats evolved from a hexaploid wild oat species composed of A, C, and D genomes with *Avena sterilis*, *Avena fatua*, or *Avena hybrida* all hypothesized as the progenitors of domesticated oats.

Domestication and Early Cultivation

Although it is not certain where the center of origin for oats is located, the greatest genetic diversity encompasses the Canary Islands, the Mediterranean, the Middle East, and the Himalayan region.

Avena species were identified at several sites in the Near East dating from 10 500 to 5750 BC. The Neolithic revolution spread from the Near East to the European Continent, Great Britain, and east to Asia. By 2000 BC, farming and trading prospered in Europe. Wheat and barley seed moved into these regions bringing oats and rye as weed contaminants. Although the historical record is limited, cultivated oats were identified in northern regions of Western Europe between 4500 and 400 BC when the region experienced cool and wet climatic changes. Oats and rye were favored in these conditions compared to wheat and barley. There are references about oats for fodder, animal feed, human food, and medicinal properties by Greek and Roman authors ~AD 23–79.

Oat cultivation continued during the Dark Ages and by the Renaissance, oats was ranked fourth in importance after wheat, barley, and rye. Oat was the dominant crop in Scotland by the thirteenth century. Oats could flourish in areas where wheat and barley produced marginal yield and became known as a crop that could be produced on less productive land. Although the primary use of oats was for animal feed, by 1500–1700 it was the principal grain crop for human consumption in Scotland, Wales, Ireland, and Britain. Oats also continued to be an important

feed for horses, cattle, and sheep. During the potato crop failure in Ireland during 1740–1741, oats were used in soup to sustain the hungry.

Immigrants and explorers from Great Britain and Spain introduced oats into North America. The English introduced oats into Canada, New England, and eastern USA in 1500–1600 as an animal feed. Scottish immigrants to North America continued to use oats for porridge and other foods. The Spanish brought oats to the Pacific Coast, the southwestern, and southeastern USA in the early 1800s to feed their horses. The general public continued to use oats for the sick, purchasing the product at chemists. Oat production moved west to the Upper Mississippi Valley and into Canada by the 1880s. Oatmeal as a breakfast food began to flourish by 1900 in USA because local mills began milling oats for breakfast cereal and the product was now sold in grocery stores instead of pharmacies or chemists.

Governor Phillip introduced oats into New South Wales, Australia in 1791. The primary use of oats was green fodder and hay for horses, dairy cattle, and pigs. Oat varieties, introduced from Europe, were late maturing in Australia, so successful production was primarily in Tasmania and the elevated regions of mainland Australia until the early maturing variety Algerian was introduced for lower rainfall regions. Human consumption of rolled oats was associated with immigrants from Great Britain. Leonard and George Parsons emigrated from England to Australia in 1861 and by the late 1880s, began manufacturing the John Bull brand of rolled oats. In 1854, Harry Clifford Love emigrated from Dublin to Australia. After several businesses, Harry and his son Joseph formed the Imperial Manufacturing Company, which began producing the Uncle Toby's brand of rolled oats in 1893.

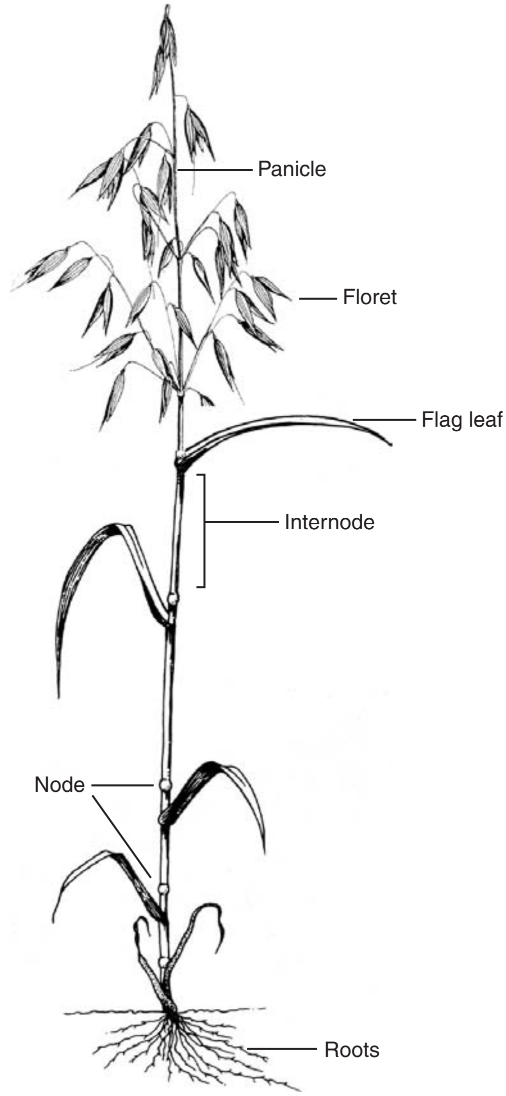

Figure 3 The main morphological parts of an oat plant.

Plant Growth and Morphology

Oats are an annual crop with tall and short stature depending on the presence of dwarfing alleles. Each plant produces about five stems depending on the growing season and each stem produces about five to six leaves on dwarf stature plants and eight to ten leaves on tall plants (Figure 3). Each stem or culm produces a terminal panicle where the seeds develop. Plant height will vary with growing season and the presence or absence of dwarfing alleles. Varieties with dwarfing alleles will vary in height between 45 and 70 cm in Australia. Tall varieties without dwarfing alleles will vary in height between 70 and 135 cm in Australia. Root development is fibrous and will vary according to aboveground growth as well as maturity, but is ~1 m deep.

Temperature and daylength influence the length of the growing period for producing oat grain. Winter and spring oats differ by vernalization requirements. Winter oats require cold temperatures to produce grain whereas spring oats will produce grain without the vernalization period. Due to mild winter temperatures in the Mediterranean climates of the southern and northern hemisphere, spring oats can be sown in the winter season.

The major developmental stages of plant growth are germination, leaf production, tiller production, stem elongation, panicle development and emergence, anthesis, grain filling, and ripening. When the seed germinates, starch reserves in the seed provide energy for root and leaf development until the plant begins to photosynthesize. Leaves develop at regular intervals until panicle emergence. Tiller production begins

when the seedling has three to four leaves. The number of tillers that live to produce grain is dependent on environmental conditions as well as the age of the tiller. Internodes of the plant begin to elongate when about four to seven leaves are present, resulting in increased height of the plant. Preanthesis panicle development occurs when the growing point is less than 1 mm. As the internodes elongate the developing panicle grows upward. Unlike wheat, barley, and rye, oats form a panicle composed of branches with the seed produced at the tip. Flowering or anthesis occurs when pollen is shed on the feathery stigmas enclosed by the lemma and palea with outer tissues called glumes (Figure 4). This stage occurs when the panicle has fully emerged from the flag leaf in tall varieties, but may occur while the head is still contained in the flag leaf for dwarf varieties. Fertilization occurs within 24 h. Grain size and weight increase as sugars are converted to starch. As the seed matures, the plant begins to lose moisture and senesces.

The mature oat grain consists of a groat or caryopsis tightly covered by a hull or husk previously the lemma and palea (Figure 5). The hull represents ~30–40% of the total grain weight. It is comprised of cellulose, hemicellulose, and lignin. Compared to other cereals, the oat groat is slender and covered with hairs or trichomes under the hull. There is a groove on the inner surface of the groat.

The groat is composed of three major fractions, bran, endosperm, and germ. Several layers of compressed tissue, and aleurone cells constitute the bran located in the outer layers of the groat (Figure 5). The aleurone cells represent the largest component of the bran and play a role in seed germination. The endosperm represents from 55% to 80% of the groat. It is composed of starch, protein, lipids, and the major concentration of β-glucans. The endosperm provides nutrients for the growing embryo. The germ or embryo has three structures, the scutellum, plumule, and radicle. The scutellum is located between the embryo and endosperm and is involved in germination and food transfer. The plumule has two to three leaf primordial and the radicle has two to three root primordial.

Growing Oats – Agronomy

Good management practices are necessary to realize the genetic potential of oat varieties. Sowing reliable seed, using optimum sowing and fertilizer rates, and timely disease and pest control constitute good management practices.

Soil Factors

Oats tolerate a wide range of soil types. The crop will tolerate acid soils to a pH of 4.5 and alkaline soils to a pH of 8.5, but optimum productivity occurs with pH range from 5 to 6. Acid soils can be associated with aluminum toxicity in oats. Oats are not as tolerant of salt as wheat, barley, and rye, but are more tolerant than sorghum. The crop is also not as tolerant of high boron levels as wheat or barley, but is similar to sorghum. Oats are generally tolerant of high manganese levels in the soil.

Climate

The most significant climatic factors affecting oat productivity are temperature and moisture. Oats flourish in cool moist environments and require more moisture to produce a unit of dry matter than other cereals. Oat-producing regions in North America, Europe, and Asia are primarily located between 40°N and 60°N latitudes. Maritime climates in northern Europe are also oat-producing regions. The length of the growing season in the northern hemisphere varies from 90 to 110 days with decreasing daylength as the growing season progresses. Prime oat-growing regions in the southern hemisphere occur within the latitudes 20°S and 45°S. Oats are grown between 30°S and 40°S latitudes in Australia, between 25°S and 45°S latitudes in New Zealand, and between 20°S and 30°S latitude in South America. The growing season in Australia and South America can vary from 150 to 180 days with increasing daylength as the growing season progresses.

Although oats tolerate cold in seedling and tillering stages, yield loss can result once the panicle emerges. However, oats tolerate frost better than wheat and barley. Hot dry weather can also reduce grain yield and quality especially from anthesis to grain filling.

Agronomy

Spring varieties are primarily sown in the southern hemisphere during the winter months. Both spring and winter varieties are grown in the northern hemisphere and time of sowing will vary with latitude. Sowing rates are dependent on a combination of climate, soil conditions, and use of the crop. Sowing rates are higher for fodder production when compared to grain production. Seed size also varies extensively in oats. Hence, sowing rates need to be calculated as number of seeds m^{-2} rather than weight of seeds m^{-2} to achieve optimum plant density.

Adequate nutrition of oats is essential to achieve maximum yields. Inputs such as nitrogen, phosphorus, potassium, and sulfur are applied based on soil tests. Micronutrient deficiencies for copper, zinc, manganese, molybdenum, and iron occur in some soils. Micronutrient toxicity for boron, aluminum, and manganese also occurs in some soils.

Oats generally tend to be more sensitive to herbicides than wheat or barley. Sensitivity is also variety dependent.

A harvester is used to cut standing plants and threshes the grain from the plant. Wind rowing is another option for harvest and requires that plants are cut and put into rows for grain threshing at a later date.

Growing Oats – Diseases and Pests

A wide range of pests and diseases caused by fungi, bacteria, viruses, nematodes, and insects affect all stages of plant growth, resulting in reduced grain yield, dry-matter production, and decreased grain quality. Control measures include genetic resistance, chemical control, and management practices. This brief overview summarizes the major diseases and pests in oats. (*see* **Cereals**: Grain Diseases) for a more comprehensive summary of cereal diseases.

Diseases Caused by Fungi

Powdery mildew caused by *Erysiphe graminis* D.C. ex Marat f. sp. *avenae* Marshal is an important disease in cool humid climates such as Northwest Europe. Stem rust caused by *Puccinia graminis* Pers. f. sp *avenae* Erikss. & Henn. (Figure 6) and crown or leaf rust

Figure 6 Oat stem rust.

caused by *Puccinia coronata* Cda f.sp. *avenae* Eriksss. (Figure 7) are the two most devastating foliar diseases in oats. Significant grain yield and quality losses result from infection. It occurs in both the northern and southern hemispheres where oats are sown. Genetic resistance is the preferred means of control for these diseases.

Figure 7 Oat leaf rust.

Figure 8 Pyrenophora leaf blotch of oats.

Although septoria leaf blotch (caused by *Septoria avenae* f.sp. *avenae* Frank.) is considered a minor disease compared to stem and leaf rust, the disease causes significant yield losses when it occurs. The disease is reported in eastern Canada, USA, Australia, Europe, Great Britain, and Israel. Pyrenophora leaf blotch caused by *Pyrenophora avenae* Ito & Kuribayashi apud Ito occurs worldwide with varying economic significance (Figure 8). Pyrenophora was the third most important disease in Germany, significant in Brazil, and common in Scandinavia. Red leather leaf caused by *Spermospora avenae* Sprague & A.G. Johnson is a minor disease identified in northwestern USA, Turkey, and Australia.

Diseases Caused by Bacteria

Halo (*Psuedomonas syringae* pv. *coronafaciens*) and stripe blight (*P. syringae* pv. *striafaciens*) are collectively called bacterial blight (Figure 9). The disease is common while cool, moist conditions persist. Severe foliar symptoms develop on susceptible varieties. Dry conditions limit the spread of bacterial blight.

Diseases Caused by Viruses

Barley yellow dwarf virus is the most yield-limiting viral disease of oats and is an economic threat worldwide (Figure 10). The virus is transmitted by a number of aphid species.

Nematodes

Cereal cyst nematode (CCN), *Heterodera avenae* Wollenweber, causes a serious economic threat to oat production worldwide (Figure 11). In regions where CCN is abundant, genetic resistance reduces CCN population sizes and oat varieties with genetic

Figure 9 Bacterial blight in oats.

tolerance ensure maximum productivity. Genetic resistance and tolerance are independently inherited.

Stem nematode, *Ditylenchus dipsaci* (Kuhn) Filipjev, limits oat production in cool moist climatic conditions (Figure 12). Winter oats sown where mild winters occur and spring oats sown in the winter (Mediterranean climates) are affected by the nematode. Resistance and tolerance appear to be more closely associated for stem nematode than CCN.

Figure 10 Barley yellow dwarf virus in oats.

Root lesion nematode, *Pratylenchus neglectus*, affects oat crops in Europe, Iran, USA, and Australia. Yield losses up to 37% were recently demonstrated in South Australian trials where the nemtode population was high. Resistance and tolerance mechanisms are inherited similar to CCN.

Insect Pests

Russian wheat aphid (*Diuraphis noxia*), greenbug (*Schizaphis graminum*), bird cherry aphid (*Rhopalosiphum padi*), grain aphid (*Macrosiphum avenae*), and rose grain aphid (*Metopolophium dirhodum*) can attack oats with varying effects on productivity.

Army worm (*Phalaenidae* spp.), fruit fly (*Oscinella frit* (L.)), and wireworms (*Agriotes* spp.) are insect pests that affect oat production in varying capacities worldwide.

Processing Oats

In order for oats to be processed, the hull must be removed from the groat, contaminants removed, and a product produced with quality appearance and taste. There are specifications for milling oats that include hull to groat ratio, color, and flavor.

Milling and processing operations consist of cleaning, grading, hulling, hull and fine separation, groat separation, and kilning (Figure 13). Grading occurs when groats are separated into two or three streams based on groat length or thickness. The hulling process is the next step when groats are separated from the hull using either impact- or stone-hulling systems. Impact hulling is more common than stone hulling.

Figure 11 Cereal cyst nematode affected plants are yellow and poorly developed.

Figure 12 Symptoms of stem nematode in an oat plant.

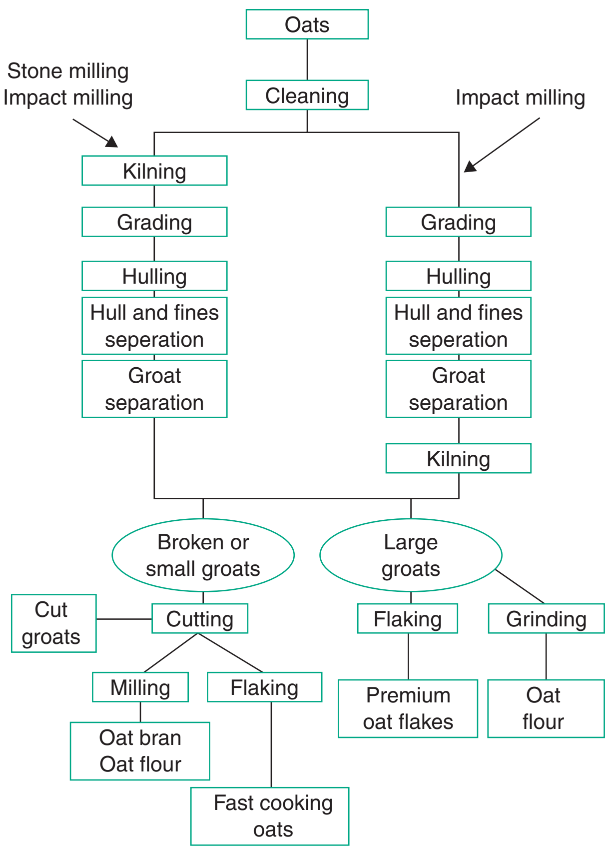

Figure 13 The milling process of an oat kernel.

Hulls and fines are separated from whole groats, broken groats, and unhulled oats. Further refinement occurs when groats are separated based on physical characters, such as groat size and weight. Because oat groats have a high oil content, a heat treatment is required to inactivate enzymes that cause rancidity and bitterness in the final product. Kilning is a process that heats the groat at a certain temperature and moisture content to inactivate the enzymes. Kilning can occur before grading or after groat separation (Figure 13).

Commercial processors generally can produce 100 kg of product from 175 kg of oats. Milling efficiency varies according to the variety and the mill-operating efficiency. Products produced include steel-cut groats, rolled oats, quick oats, baby oats, instant oat flakes, oat flour, and oat bran.

Using Oats

Oats are a versatile crop used as grain and fodder for animal feed, human foods, industrial products, cosmetics, and pharmaceuticals. Figure 2 shows the diversity of oat products relative to the proportion used. Animal feed is the largest use of oats; cereal products and other human food the second most common use. Although pharmaceuticals represent the smallest group of products, they have the greatest potential for future growth and value.

Oats for Feed Grain

Oats have been a traditional feed grain for centuries. Recent advances in corn, wheat, barley, soybean, and canola as feed grains have resulted in a worldwide decline of oat production for feed. Despite the decline, the primary use of oats remain as a feed grain. Prior to mechanization oats were the primary feed for horses that powered farm equipment. Oats are a suitable feed for dairy and beef cattle, sheep, and horses. Although not as prevalent, oats can also be used for poultry, pigs, cats, dogs, birds, rabbits, bison, deer, and fish. In recent years, naked oats are being developed as a feed grain with improved nutritional value for markets such as weaner and grower pigs, poultry, racehorses, and birds. The following discussion centers on the traditional oat grain possessing a hull.

The nutrient value for animal feed is based on the proportion of groat to hull. The ratio varies with variety and environment. Oat groats have a higher oil or lipid content than other cereals, varying between 3% and 11%. The oil is comprised primarily of unsaturated fatty acids, which can alter the fatty acid composition of the animal fat. Protein content in oat groats varies from 9% to 15% with higher lysine content than corn, wheat, and barley. Lignin is the primary fiber fraction of the hull and reduces grain digestibility in animals. Lignin content also varies in different varieties. Although hulls with high lignin reduce digestibility, varieties with lower-hull-lignin content can have a beneficial affect for horses, cattle, and sheep. The hull reduces digestive problems in these animals.

The hull is a major constraint as a feed grain for poultry and pigs. It reduces digestibility resulting in low protein and poor energy. Because naked oats do not have a hull, the grain provides a good source of energy for grower and weaner pigs, broilers, and laying hens.

Overall, oats are a favorable feed for ruminants such as cattle and sheep. Oats are also the preferred feed for horses due to the palatability, digestibility, and nutritive value of the grain. Naked oats are also used for racehorses, due to the limited requirement of grain intake and the need for a good source of energy.

Oat Grain for Human Consumption

Products produced from oats are generally made with the whole grain after the hull is removed, whereas other cereal products are produced from grain with the germ and bran removed. Whole oats have the highest protein and a favorable ratio of unsaturated to saturated fatty acids compared to other cereals. Whole oats also provide vitamins, minerals, and antioxidants. The heat treatment used to stop rancidity also enhances the unique sensory characters of oats.

The unique composition of whole oats results in healthy products. β-glucan content in the groat varies between 1.8% and 7.5% on a dry matter basis. The high level of water-soluble dietary fiber of which β-glucans are the main component, helps to reduce high blood cholesterol and normalize blood glucose levels. The fiber also reduces the risk of colorectal cancer. The groat also contains vitamins and antioxidants. Lactose intolerant individuals can now purchase nondairy oat products.

The main product produced from oats is porridge or oatmeal. Other food products processed from oats are cold cereals, infant foods, muesli or granola bars, breads, biscuits or cookies, thickeners, and specialty flour. New processes were developed recently to manufacture nondairy products such as milk, ice cream, and yogurt using oats. Antioxidants in oat flour can be used to stabilize some milk and meat products sensitive to fat oxidation during storage. Oat gum primarily composed of β-glucans is used to stabilize ice cream. Oat proteins have been used in many food products including heat resistant chocolate, because of viscosity and emulsification properties.

Oat Grain for Industrial and Nonfood Uses

There are many potential uses of oat grain fractions and hulls in products such as adhesives, cosmetic products, pharmaceuticals, and oil-spill cleanup. Some of the uses are proposed, whereas the technology for other uses has been developed and implemented.

The unique chemical composition of the oat groat is responsible for oat starch gels having more elastic, adhesive, and translucent properties than wheat or maize starches. Oat starch could replace products produced from wheat or maize with the waxy starches the exception. Products currently produced from starch include brown paper and cardboard products, and coating agents for tablets in the pharmaceutical industry.

Oats have been used in cosmetic products for some time. The starch characteristics make oats an useful ingredient in bath products to relieve itching and nappy rash. Other products produced from oats include cleansers to replace soap in facial masks, soap for cleansing dry and oily skin, shampoo, lotions, bath additives, and skin care.

Pharmaceutical products have great potential, but are not currently tapped. The health benefits of oat fractions were discussed in the section above.

The hull can also be used to produce industrial products. Oat hulls are used to produce furfural and furan compounds. These compounds are used in the manufacturing process of: crude petroleum; nylons; formaldehyde furfural resins; solvents for dyes, resins, lacquers, paints and varnish; elastomers and thermosplastics; phenolic resin glues and plywood adhesives; construction board material; and cellulose pulp. A very different aspect of hull utilization is the cariostatic properties of tooth protection.

Oats for Fodder

Fodder production is also an important component of animal feed shown in Figure 1. Several types of oat fodder, hay, silage, grazing, and straw, are produced as an essential component of animal production systems worldwide.

Oat hay is produced for dairy and beef cattle, horses, and sheep. Hay is an important commodity domestically, but is also traded internationally. A significant market is the Asian dairy and beef cattle industry. The oat hay crop is cut at the early milk growth stage for optimum hay quality. Hay-quality characters that may be associated with palatability are digestibility, water-soluble carbohydrates, acid detergent fiber, and neutral detergent fiber, and stem diameter. Sensory quality characters are also important and include hay color and aroma.

Cattle and sheep graze oats during the vegetative stage when the plant height is from 20 to 40 cm. Animals are removed from the oat crop before the growing point of the plants is damaged, so the crop produces grain. Grazing is important in countries worldwide including New Zealand, Australia, South America, northern Africa, Nepal, and the USA.

Silage production using oats is used in the dairy and beef cattle industry worldwide. Oats are cut in the early heading stage, chopped and ensiled.

Breeding Improved Oat Varieties

History

Early oat improvement occurred when farmers selected the best performing plants in their paddocks. The first attempt to introduce genetic variation by crossing different oat genotypes was reported in England and accomplished by Shirreff in the 1860s. The first variety developed from hybridizing oats, Abundance, was released from Gartons Ltd. of Warrington, England.

Breeding Priorities

Breeding priorities determine selection criteria that eventually result with the release of oat varieties with improved traits. Understanding production and processing constraints of oats is the initial step in identifying breeding priorities for improving varieties. These priorities will differ or change in emphasis depending on the growing environment and end use of the oat plant or grain. Breeding priorities are based on gross margin for growers and processors, resulting in a superior product for the consumer and processor. Breeding priorities set to achieve long-term goals are based on developing varieties that offer new products or increased value for both growers and industry. The long-term breeding priorities are particularly important for oats due to the global decline of production.

Although there are many different growing environments and end uses globally, the primary breeding priorities deal with productivity, disease resistance, agronomy, and quality.

Increased grain and hay yields are the primary aims of increased productivity. Improved disease resistance increases yield and enhances quality.

The significance of oat diseases vary with region and continent and are prioritized by breeding programs. Diseases such as stem and leaf or crown rust are two global diseases that cause significant losses to the oat industry. Barley yellow dwarf virus, smut, and septoria also reduce yield and quality in certain production areas of the world. Cereal cyst, stem, and root lesion nematodes when present in the production environment are equally as devastating, but more regionally localized in the world.

Important agronomic characters are standing ability, maturity of the plant, and the ability of the plant to resist shattering or loss of seed at maturity. Winterhardiness is also an important agronomic trait of the varieties that require a cold period to produce seed.

Grain-quality characters that are essential for the industry are – high groat to hull ratio and groat color. Weather and disease can cause groat discoloration. Other grain-quality characters of importance for variety development are protein, oil, β-glucan content, hectoliter weight, and screenings percent. The most important aspect of fodder quality is palatability. The traits that comprise palatability are being researched, but are most likely a combination of digestibility, water-soluble carbohydrates, neutral detergent, and acid detergent fibers, color, and smell.

Germplasm Collections

Oat-germplasm collections are maintained in many countries and are a source of new genetic variation for improving oats. Without these collections and the exchange of advanced germplasm from oat-breeding programs, oat-variety improvement would not advance. Several collections of notable importance are located in the United Kingdom, Canada, USA, Israel, the Russian Federation, and China.

OIL FROM RICE AND MAIZE

J S Godber, LSU Agricultural Center, Baton Rouge, LA, USA

Introduction

The oils from rice and maize, hereafter referred to as corn, have both similarities and dissimilarities. They are similar in that each one of them would be considered a specialty oil derived from less commonly used sources and possess unique functional/nutritional components that distinguish them, such as high levels of natural antioxidants. They are dissimilar primarily due to their fatty acid composition. Corn oil has higher linoleic acid content, whereas rice oil contains higher levels of oleic acid. This article discusses the two oils from the viewpoint of their production, processing, and utilization.

Production

Rice Oil

The level of rice production is second only to wheat, among all the cereal grains produced worldwide, yet it is a minor commodity in the US. Rice oil is obtained from the bran composite that is removed during the milling of brown rice to produce white rice. In actuality, the oil is found primarily in the germ, which represents ~2% of the rice kernel (Figure 1). However, in typical rice milling operations it is not possible to separate the germ from the bran, so the resulting product, commonly called rice bran, contains the germ as well. Rice bran, which represents ~8% of the whole grain weight, contains ~20% lipid, with a range from 15% to 25%. Thus, it represents a considerable resource when considering the world production of rice. However, only ~8% of the world's potential rice oil production is realized, amounting to ~7 million metric ton (Mt) in 1998. There are two primary reasons that a greater proportion of the potential rice oil production fails to be attained. The first is that in most of the countries that produce large quantities of rice, such as China and India, rice is milled in ways that do not separate the outer hull from the bran and germ layers. This

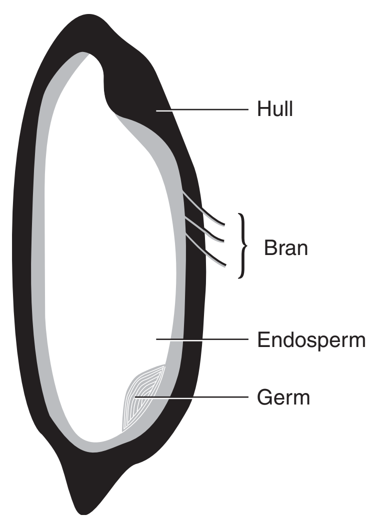

Figure 1 Rice grain.

makes the extraction of oil more difficult and not as economical. The second reason is that, even in mills that possess the capability of separating hull from bran and germ, the bran fraction is highly unstable and if not stabilized or extracted immediately, would yield oil of such low quality that it would not be suitable for human consumption. The reason for this instability is that the rice grain possesses highly active lipolytic enzymes that cause both oxidative and hydrolytic degradation of the lipids. Lipases tend to be the main culprit, causing a very rapid rise in free fatty acids that result in off-flavors, and are more susceptible to oxidative reactions and increase refining costs. Lipoxygenases can accelerate lipid oxidation, which primarily results in off-flavors, but can also degrade fat-soluble vitamins and generate toxic compounds.

Rice oil is generally produced from stabilized bran. Bran is stabilized in a number of ways, but usually involves the elevation of temperature that denatures the enzymes responsible for lipid degradation. A popular means to stabilize rice bran is to pass it through an extruder so the frictional energy generated through the process of forcing the bran through the small orifice of the extruder plate causes an increase in the temperature. Temperatures required for adequate stabilization are generally believed to be more than 120°C. Other means of stabilization include pH adjustment using weak acids, microwave heating, and irradiation; however, no other practical methods have been utilized commercially.

Until recently, rice oil was primarily produced only in Japan. India has also begun a program to increase the utilization of rice oil. In 1993, the Riceland Foods Cooperative (Stuttgart, Arkansas) in collaboration with a Japanese company, Itochu Corporation, began producing rice oil for commercial distribution in the US.

It should be noted that defatted rice bran, which would become a by-product of rice oil production, does not have the full health benefits such as hypocholesterolemic properties associated with full-fat rice bran. This is due to the removal of functional components such as vitamin E vitamers (tocopherol and tocotrienol homologues) and oryzanol. However, defatted rice bran is more stable for human food processing and possesses high levels of fiber and other potential health-promoting compounds.

Corn Oil

Corn is one of the three major cereal grains grown in the world, along with rice and wheat. Like rice, it is a major staple in regions of the world outside of the US, yet is a minor food commodity in the US; rather, it is primarily used as animal feed. Corn oil is primarily a by-product of the corn milling industry, which processes ~10% of the total world corn crop. As with rice oil production, the primary source of oil in corn is from the germ. Although it is possible to extract oil from corn bran that is separated from the germ, the amount of oil extracted would be much lower and its composition would be different from the corn oil that is typically extracted from milled corn.

The germ of corn is relatively larger than in most cereal grains, comprising ~10–14% of the seed weight (Figure 2). The bran consists of the first few layers of tissue and comprises ~5% of the seed weight. The germ contains ~35% oil, although varieties of corn have been developed in which the level of oil in the germ can approach 50%, whereas the bran would contain ~1% oil.

There are two types of milling, wet and dry, each of which produces different products and from which oil quality and yields vary according to the processing methods employed. The primary goal in dry milling is to produce prime endosperm products such as corn meal, grits, and flour. The primary goal of wet milling is to produce corn starch, which could also be processed further into corn sweeteners or ethanol. With the increasing importance of modifying starch or converting it to high-fructose corn syrup for applications in the food industry, wet milling has become predominant. Oil yields tend to be higher from wet milling (4%) compared to those from dry milling (2%).

Corn germ from dry milling is similar to rice bran in that it tends to be unstable due to the presence of lipolytic enzymes, which must be inactivated by cooking. Both dry- and wet-milled germs are generally dried to a moisture content of 3% and are then flaked prior to extraction.

The history of corn oil manufacturing in the US is much longer than that of rice oil. The reader is referred to the Mazola corn oil website for an interesting depiction of the history of corn oil in the US.

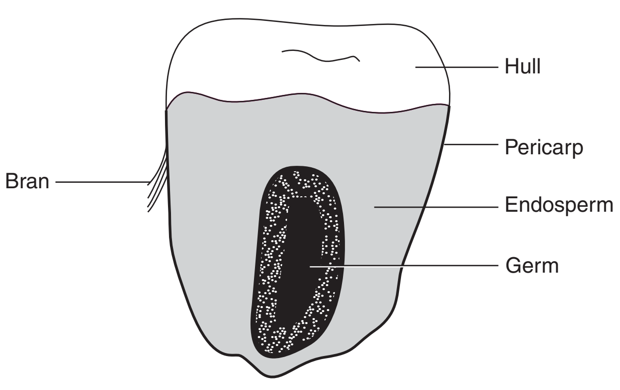

Figure 2 Corn grain.

Processing

Rice Oil

Extraction Rice oil is typically extracted with solvents. The traditional solvent of choice has been hexane, although concern for impending, regulatory scrutiny of hexane for environmental and toxicological reasons has prompted exploration of alternative approaches to extraction. Although it is possible to extract oil from bran through mechanical means via pressing, oil recovery is lower and costs higher compared with solvent extraction. It has been found that pelletizing the fine rice-bran particles aids in the percolation of solvent through the bran during solvent extraction and increases yield. Alternative solvents have been considered, including ethyl acetate, isopropyl alcohol, and acetone. However, currently these are not as economical as hexane, although if regulatory action is taken with regard to hexane, these solvents may become the only viable option. At an academic level, supercritical fluids have been evaluated as a potential means to extract oil from rice bran. In principle, this approach offers interesting advantages such as ease of solvent removal and lack of toxicity. Also, it is possible to obtain fractionation of oil during the extraction process, which could facilitate refining or production of nutraceuticals. The major obstacles to the use of supercritical fluids are the large capitalization cost of initial startup and safety concerns due to the high pressures involved. Again, regulatory actions may necessitate such approaches in the future.

Refining Following extraction, several processes are undertaken that are collectively referred to as "refining" in order to improve the quality of the oil. The refining process may also cause a reduction in nutritionally active compounds such as vitamin E and oryzanol, which may be recovered as by-products of the refining process. Generally, the first step in the refining process is dewaxing. Crude rice oil can have up to 8% wax, depending on the extraction method. Such high levels of wax can have an adverse effect on subsequent refining steps causing reduced yields, and can cause problems with refining machinery. A common practice is to allow crude oil to sit in settling tanks to allow the higher-melting-point waxes to settle out. After removal of the oil, these waxes can be recovered and may have value as a by-product. The next step is the removal of the phosphatides by water washing, which is referred to as degumming. Again, this step is carried out early in the refining process so as to avoid problems with subsequent refining steps and machinery. A by-product of this step would be lecithin.

Perhaps the most critical step in the refining of rice oil is the neutralization step. This is because of the propensity for rice bran to undergo hydrolytic rancidity with the accumulation of free fatty acids. High levels of free fatty acids can lead to quality problems related to color and other physical properties. Free fatty acid neutralization is normally accomplished using sodium hydroxide or other caustic compounds such as sodium carbonate. The amount of caustic material used is dependent on initial free fatty acid levels. In crude oils with high levels of free fatty acids, it may be necessary to include physical refining by distillation of free fatty acids in order to increase yields to an acceptable level. A by-product of the neutralization process is soap stock, which is obtained after water washing. In addition to its obvious potential for the production of industrial soaps, soap stock can be an excellent source of a class of compounds called oryzanols, which may have unique health benefits. Furthermore, oryzanol can be maintained at much higher levels in the oil by only physically refining, rather than caustically refining, the oil. Because of the health benefits associated with oryzanol, this approach has been advocated as a way to maximize the potential health benefits of rice oil.

Bleaching using clay or diatomaceous earth can be done to remove color, and deodorization by counter-current steam is employed to remove volatile substances. By-products of these steps include tocopherols, tocotrienols, and carotenoids, each of which has potential health benefits. Other finishing steps could include hydrogenation to reduce unsaturated fat and hardening of the oil, and winterization to remove the remaining high-melting-point glycerides and waxes.

Corn Oil

Removal of oil from the wet-milled corn generally involves a combination of expelling and extraction. Initially, expelling is employed to reduce the oil content from $\sim$50% to $\sim$20%, after which solvent extraction is used. Dry-milled germ, which has generally been cooked in order to stabilize it, is then flaked and extracted with solvents. Refining steps for corn oil production are similar to those for rice oil. However, crude corn oil does not have the high levels of waxes found in crude rice oil, which simplifies the refining process, although it must also be degummed to remove the phospholipids prior to further refining. Also, because corn oil is promoted as a salad oil, the winterization process is critical in order to greatly reduce high-melting-point glycerides and waxes. Like rice oil, corn oil tends to have high levels of vitamin E vitamers, especially tocopherols, which could be an

important by-product of oil refining. Also, corn has higher levels of carotenoids such as lutein and zeaxanthin, which are receiving considerable attention as compounds that could reduce the eye disorder called macular degeneration. Thus, recovery of these carotenoids from the refining process could also be valuable.

Utilization

Rice Oil

In the US, rice oil has not been produced in large quantities, and is therefore more of a specialty item found primarily in international food stores and some health or gourmet food shops. In Japan, rice oil is a preferred cooking oil due to its delicate flavor and textural properties. Also, it has been suggested that food cooked in rice oil has a longer shelf life because of the natural abundance of antioxidant compounds. Additionally, recent evidence that rice oil may possess health-promoting properties has increased interest in developing commercial applications. A patent has been granted that describes the use of rice oil in blends with less stable oils, such as soybean oil, in order to increase overall stability. Another patent has been granted for the incorporation of rice oil into mayonnaise in order to reduce cholesterol absorption from mayonnaise-containing food. Rice oil may also be ideal for use in margarine. Because of its lower level of unsaturated fatty acids, it would require less hydrogenation, which would reduce *trans*-fatty acids. Also, rice oil has a natural tendency to produce more stable beta prime crystals, which would give rise to a smoother, creamier texture. Rice-oil-based margarine could be an alternative to recently released cholesterol-lowering margarines that contain phytosterols or stanols. Rice oil has a naturally high abundance of these compounds, whereas some of the currently available products have incorporated phytosterols from other sources such as pine tar.

The combination of unique sensory properties and functional applications for rice oil, along with potential health benefits, has increased the utility of rice oil as a viable commercial entity. In addition, rice oil possesses a unique abundance of components that have commercial potential as valuable by-products. As previously mentioned, these include waxes, lecithin, oryzanols, tocopherols, tocotrienols, and carotenoids.

Waxes tend to be difficult to isolate and purify; however, the high concentrations of wax in rice oil could be potentially valuable if more efficient methods of purification could be developed. Combining supercritical fluid extraction with fractionation offers some hope in this regard. Waxes are primarily used in nonfood applications; however, recent evidence suggests that certain long-chain alcohols found in wax could have health benefits. Crude rice oil also tends to be high in gums, which could have commercialization potential if appropriate recovery processes were developed. Currently, much of the lecithin production comes from the soy-oil-processing industry, where economies of scale make it a more economical source. However, the reputation of rice as a nonhypoallergenic food could provide an alternative to soy lecithin. Oryzanols are an interesting class of compounds made up of triterpene alcohols, including sterols and stanols, esterified to the phenolic compound ferulic acid. Crude oil can have up to 2% oryzanol, which can be concentrated during processing. However, oryzanol does not currently have Food and Drug Administration (FDA) additive status, which limits its commercial application beyond its normal existence in rice oil. As such, it has been touted as an antioxidant and for its potential to lower serum cholesterol. Tocopherols and tocotrienols are considered vitamin E vitamers (i.e., possess vitamin E activity), but tocotrienols may have unique health benefits such as lowering serum cholesterol and exhibiting anticancer activity toward certain types of cancer such as breast and colon cancer. Rice bran oil is one of the richest sources of tocotrienols, especially the gamma homologue, for which the greatest health benefits have been suggested.

Corn Oil

Corn oil has been promoted traditionally, based on its light color and texture, as an ideal salad and cooking oil. It also tends to have good flavor stability and a high smoke point, which makes it a good choice for fried foods. Corn oil margarine is another product, well known for its perceived health benefits related to low saturated fat and high linoleic acid content. As previously mentioned, by-products from refining corn oil include the tocopherols from deodorizer distillate and carotenoids from bleaching. Recent research has revealed that the oil obtained from corn fiber generated during wet milling is very high in ferulate esters of sterols and stanols, similar to the oryzanol component of rice bran.

Quality Factors

The fatty acid composition of rice and corn oil is depicted in Table 1. Rice oil contains more oleic and palmitic acids than does corn oil; the linoleic acid content is, however, less in rice oil. Both are very low in linolenic acid, which in part contributes to their oxidative stability and utility as frying oils.

Table 1 Composition of major fatty acids in rice and corn oil

Fatty acid (common name)	*Rice*	*Corn*
Myristic (C14:0)	<1.0	<1.0
Palmitic (C16:0)	12–18	9–14
Stearic (C18:0)	<3.0	0.5–4
Oleic (C18:1)	40–50	24–42
Linoleic (C18:2)	29–42	32–62
Linolenic (C18:3)	<1.0	<2.0

Table 2 Quality factors for rice and corn oil

Oil	*FFA (%)*	*Nonsaponifiables (%)*	*Peroxide value (meq kg^{-1})*	*Iodine value*
Corn	1.5–4.0	<2.0	0.3	103–133
Rice	3–15	6–8	0.6	92–115

As stated previously, rice and corn oils are rich sources of a variety of compounds that may have health benefits. Both are unique in their high concentrations of vitamin E vitamers. Corn oil tends to be higher in tocopherols, whereas rice oil is higher in tocotrienols; in both cases there is an especially large concentration of the gamma homologue. Both also contain relatively high levels of ferulic acid esters, although rice oil has higher levels of dimethyl triterpene alcohol forms and corn oil is higher in sterol forms.

Typical oil quality standards are shown in Table 2. Rice oil has a much higher level of free fatty acids than corn oil, which is a reflection of the susceptibility of rice oil to hydrolytic cleavage by active lipases. Also, the nonsaponifiable fraction of rice bran oil is quite high compared with corn and most other grains. This is due to the high concentration of tocopherols, tocotrienols, oryzanols, and especially phytosterols. Rice and corn oils have very low peroxide values, which is a reflection of their excellent oxidative stability. The higher degree of unsaturated fatty acids in corn oil is seen in its higher iodine value.

Conclusion

Rice and corn oils have distinctive characteristics that lend themselves to commercial utilization, but both tend to be underutilized relative to total world production of the cereals from which they are derived. Also, both could potentially generate a wide variety and abundance of valuable by-products during their production and processing. Since both are by-products of the milling of cereals to produce other primary products, increasing their utilization would depend on changes in the milling process itself. In the case of rice, more efficient milling processes that at least separate bran from hulls and possibly germ from bran would be needed. Also, processing systems would be needed that could rapidly stabilize and/or extract the bran in order to prevent lipid degradation. In the case of corn, the primary limitation is the low level of milling currently practiced in the corn-production and corn-processing industry. Increasing applications for milled corn products in the food industry will most likely increase the percentage of the crop that is milled. Also, the continuing consideration of corn as an alternative fuel source through ethanol production could increase the amount of milled corn available for oil extraction.

It is likely that the production and utilization of rice and corn oil will increase, especially as the population becomes more aware of their health benefits, but it is unlikely that either will ever become a major commodity.

OILSEEDS, OVERVIEW

R J Mailer, Wagga Wagga Agricultural Institute, Wagga Wagga, NSW, Australia

Introduction

Oilseed crops are generally grown for the oil in their seeds and vary considerably in oil content, quality, and composition – factors that rely heavily on the crop species or cultivar and upon the environmental conditions in which the crop is grown. The seed meal left after the oil has been extracted can provide a high-protein product for use in either animal or human food. In other crops, the seed meal or some other factor is more important than the oil and the oil is a by-product. For example, soybean is primarily grown for its high-protein meal and cotton for its fiber. Consequently, in oil-producing crops, plant-breeding programs are aimed both at increasing oil production and quality with the additional aim of increasing meal quality. In some oil crops, antinutritional components are present (such as gossypol in cottonseed and glucosinolates in rapeseed) that also need to be considered that may limit the use of the meal.

Oilseeds and Their Uses

The major use of oilseed crops is the oil, which, in many cases accounts for up to 80% of the crop value. The oil-free meal provides additional value along with various by-products such as lecithin, and a range of extracts from both meal and oil.

Vegetable oils contain 95–98% triacylglycerols (or triglycerides). The remaining fraction consists of phospholipids, mono and diacylglycerols, and unsaponifiable components including sterols and tocopherols. The oils consist of long-chain fatty acids from C14 to C24 in length and the proportion of these fatty acids in the oil has a significant contribution to its nutritional value. In recent years, there has been a trend in human diets towards reduction of saturated fats such as palmitic acid (C16:0) and an increase in polyunsaturated (C18:2 and C18:3), and monounsaturated (C18:1) fats. Plant breeders have successfully developed more nutritionally favorable products from traditional oilseed crops by altering their fatty acid profiles and other constituents.

World consumption of oils is forecast by FAO to exceed 122 million tons (Mt) in 2005. Although demand is slowing down in developed countries as they reach saturation levels, consumption in developing countries is steadily increasing. Nonfood uses of vegetable oils in developed countries are estimated to account for ~22% by 2005 due to developments in the oleochemical industries with a shift away from petroleum-based products to environmentally friendly oleochemicals. In addition, there is an increase in technological developments, particularly with the genetic modification of oilseeds to create a new range of products. For cooking oils and salad dressings, plant breeders have selected cultivars with lower levels of polyunsaturated and saturated fats and an increase in monounsaturates for increased oxidative stability. New developments include oils with increased stearic acid to provide margarine type fats without the need for hydrogenation and the subsequent production of trans-fatty acids. The uses of vegetable oils in paints, lubricants, cosmetics, and pharmaceuticals have been well documented.

World consumption of oilseed meal is expected to reach 28 Mt by 2005. Soybean meal dominates the market, forecast to account for ~63% of the global meal production by 2005. It is expected, however,

that future meal production from sunflower and rapeseed will increase relative to soybean. Much of the meal is utilized as stock feed and the production of livestock products, in particular pork and poultry and more recently, aquaculture. Meal products, such as protein extracts, are used for edible purposes and consumption of whole seed, including roasted soybeans, peanuts, and sesame seed is common. The meal also has industrial applications in cosmetics, paints, and adhesives.

Oil Analysis

The traditional methods of oilseed analysis made plant breeding and selection a slow and tedious process. The Goldfische or Soxhlet methods of oil extraction required several hours to complete and involved the use of hazardous flammable solvents. In addition, only a few samples could be processed at a time reducing the capacity of the laboratories to service the needs of plant-breeding programs. Kjeldahl nitrogen analysis to determine the nitrogen content of the meal also required the use of dangerous chemicals and strong acids. More recent advances in oil content determination include nondestructive seed analysis, such as the use of nuclear magnetic resonance (NMR) spectroscopy. The rapid and accurate nondestructive testing of seed for oil content allows the breeder to retain the seed of potentially suitable lines. The introduction of near-infra-red reflectance (NIR) spectroscopy has further enhanced the ability of laboratories to determine a wider range of seed components including oil, protein, moisture, fiber, and numerous others on relatively small samples in a short time. Consequently, hundreds of seed samples can now be analyzed each day and the intact seed returned to the breeder for further growth and evaluation.

New Variations on Old Crops

The major oilseed crops of the world include soybean, cottonseed, rapeseed, sunflower, groundnut (or peanut), sesame seed, linseed (from which the name linolenic acid is derived), safflower, and mustard seed. Many other crops can be used for oilseed production including castor beans, grape seed, tobacco seed, flax, corn oil, tung beans, and okra. The oil and protein content of the major oilseed crops is shown in Table 1.

From these crops, breeders have developed specialty oil types within the different species. Sunflower oil, for example, is traditionally high in linoleic (polyunsaturated) acid and is promoted as such for its health benefits. With further plant breeding, there are now several grades of sunflower oil, from high linoleic acid to high oleic (monounsaturated) as well as intermediate types. Oleic acid, being monounsaturated, has higher oxidative stability. In addition, the reduction in linoleic acid means that the need for hydrogenation to reduce polyunsaturated oils and the formation of trans-fatty acids is reduced. Trans-fatty acids are nutritionally undesirable and similar to saturated fats in their effects. Examples of plant species, which have been bred with increased oleic acid, include sunflowers (high oleic and Nusun™), linseed (solin, Linola™), cottonseed, soybean, rapeseed (canola, Monola™), safflower, and mustard.

Table 1 Approximate oil content of seed and protein content of oil-free meal and the main uses of selected oilseed crops

Oilseed	*Oil (%)*	*Protein (%)*	*Main use*
Soybeans	20	46	Food
Cottonseed	16	37	Fiber
Peanut	41	46	Food
Rapeseed	41	34	Oil
Sunflower seed	40	28	Oil
Sesame seed	40–60	42	Food
Linseed	40	32–34	Oil
Safflower seed	34	23	Oil
Mustard seed	20–50	35	Condiment

Adapted from Australian Oilseed Federation Technical and Quality Standards – 2002 and other literature values.

Other changes of significance to oilseed crops have been the development of genetically modified plants with specific applications other than for edible oils. The most obvious example of these is soybean in which large numbers of products are in development including those containing antibodies, altered amino acid profiles, zero lipoxygenase and others. Rapeseed is also in the process of undergoing numerous transformations to produce products for polymers and detergents, inks, cosmetics, pharmaceuticals, lubricants, plasticizers, and resins.

The Crops

Soybean Seed

The seeds are rich in protein, mainly globulins, which make up 90% of the total proteins and 36% of the seed weight. Ten percent of the seed weight is carbohydrate, mainly sugars, and 3% is starch. The seed is relatively low in oil compared to other oilseed crops at ~20%. Following oil extraction, heat treatment is used to inactivate enzymes in the high-protein meal that otherwise reduce the digestibility of the stock feed. Traditional soybean oil is polyunsaturated with 48–59% linoleic acid (C18:2) and 4–11% linolenic acid (C18:3) (Table 2). Breeding has produced cultivars with various fatty acid profiles; in particular, high oleic soybean oil, which contains up to 84% oleic, has less saturated (palmitic) acid, and is more stable for cooking purposes. The meal may also be

used for industrial purposes such as cosmetics, paints, and adhesives as well as various edible purposes.

Cottonseed

Cotton is basically grown for its fiber but the seed has several important components consisting of oil (16%), protein (37%), hull (37%), and linters (10%). Also, within the kernel is a phenolic compound called gossypol, ~1% of the seed weight: toxic to humans and monogastric animals. Cottonseed oil, prior to refining, is red due to the residual gossypol and associated products. Increased seed oil content has been a secondary objective to fiber production although the value of the oil is significant. Cottonseed oil contains ~47–58% linoleic acid. To make the oil more stable for cooking and to reduce the need for hydrogenation, the Commonwealth Scientific and Industrial Organization (CSIRO) in Australia have developed an alternative cottonseed oil. By "switching off" genes that convert oleic acid to linoleic they have been able to produce high oleic (73%), low linoleic (5%) oil with increased oxidative stability. Additionally, they have found it possible to alter the proportions of saturated fatty acids, palmitic and stearic, which provide the solid properties necessary for making margarine.

Groundnut or Peanut

Peanuts are a valuable source of oil and also produce a high-protein meal for stock feed. Increased yields are an important breeding priority, particularly in developing countries where yield is poor. Increased oil content is also desirable as peanuts have a wide range from 40% to greater than 60% in wild types. Reduction in linoleic acid produces oil with a better oxidative stability. Meal protein is high at ~46% but the amino acid profile is lacking in sulfur-containing amino acids particularly methionine. The components of whole peanuts are protein (26%), oil (41%), and carbohydrates (24%). The main product is the oil that has ~80% unsaturated fatty acids making it a nutritionally favorable oil. Additionally, the level of oleic acid and palmitic acid makes it stable with good keeping qualities for cooking and in food mixtures. Plant selection has seen the development of new cultivars with high oleic acid levels of up to 60% and a subsequent reduction in linoleic acid content. Fatty acid profiles are influenced significantly by environmental conditions with high temperatures favoring high oleic acid contents.

Rapeseed

Traditional rapeseed oil characteristically contains high levels of erucic acid, found to have detrimental effects on the myocardial muscle of rats fed the oil. The value of the meal was also low due to the presence of sulfur-containing compounds called glucosinolates, found to have deleterious effects on the thyroid gland of mono-gastric animals. Through plant breeding, major changes have been achieved to traditional rapeseed by increasing yield, oil, and simultaneously

increasing meal protein content. The development of cultivars with very low levels of glucosinolate in the meal has also been achieved. With the dramatic change in rapeseed from traditional types to those grown today, new terms have been used to discriminate between the types. Canola is recognized under ISO 5725, Codex Alimentarius and ISTA as cultivars of rapeseed with less than 2% erucic acid in the oil and less than 30 μmol of aliphatic glucosinolates in the meal. European nomenclature to describe cultivars of rapeseed include low erucic acid rapeseed (LEAR) and Colza which is the French name for *B. napus* rapeseed in general. The seed oil is the main value of the crop yielding 42% oil, while the meal contains 35% protein. Current canola cultivars have very low erucic acid and saturated fatty acids levels and a good proportion of oleic (C18:1), linoleic (C18:2), and ω-3 linolenic (C18:3) fatty acids. The balanced fatty acid profile makes rapeseed ideal for mayonnaise and salad dressings as well as a wide range of applications in the bakery and confectionary industry. New high oleic/low linolenic types have improved oxidative stability for cooking and longer shelf life. Alternatively, high erucic oil is utilized for industrial purposes such as cutting oils. Erucic acid is extracted from high erucic rapeseed and converted to erucamide for plastic manufacture.

Sunflower

Sunflower is grown for the seed oil, which is ~80% of the seed value. The de-hulled meal has 28–42% protein. The oil is highly considered due to its low linolenic acid value and therefore oxidative stability for cooking, salad oil, and margarines. Heritability of high oil is reliable and it has been possible to increase oil contents from 30% in early types to over 50% in recent years. Sunflower cultivars with a range of fatty acid profiles have been developed including high oleic acid (75–91%) with reduced levels of linoleic acid (2–17%) and high levels of alpha tocopherol (vitamin E), providing the market with very stable monounsaturated oil for cooking purposes. Mid-oleic cultivars are also available, such as NuSun™, with saturated fatty acid levels of 8% and only 20–30% linoleic acid. The meal has high protein content and is used in animal feed for livestock and poultry. A small percentage of the crop is used for nonoilseed production for confectionary purposes.

Sesame Seed

Sesame seeds are used intact or as oil and meal. The seeds generally have high oil content of ~50% and ~25% protein, although the oil content can vary between 40–60%. The fatty acid composition also shows a large range (Table 2). A high oleic (40%) and linoleic acid (45%) content makes the oil nutritionally beneficial. The unsaponifiable fraction of the oil contains sesamine and sesamoline that during the refining process form sesamol and sesaminol. These are strong antioxidants that give the oil exceptional resistance to oxidation and rancidity. The oil-free meal is high in protein (34–50%), depending on the variety, and has a favorable amino acid profile with high methionine and low lysine content. Today the seed is used for human consumption on bread rolls, health food and confectionary.

Linseed

Due to its high iodine value, linseed oil has been used primarily for industrial purposes, such as linoleum floor covering, with a high level of unsaturated fatty acids making the oil very reactive and resulting in a short shelf life. Low linolenic acid cultivars have introduced linseed to the edible food market. In 1994, the Flax Council of Canada developed the term “Solin” to describe linseed with less than 5% linolenic acid. The original hybridization work was carried out by the CSIRO in Australia with the release of two Linola cultivars in 1992 under the Plant Varieties Rights Scheme. Linola 947 was the first Solin cultivar registered in Canada. Solin cv. Linola™ 989 has been reported as 46% oil (dry basis) and 34% protein. Linseed meal has a high crude protein value but low lysine levels. It also has a high level of soluble fiber, called mucilage that is indigestible to nonruminants and reduces the energy value of the meal. Linseed is traded at 40% oil although the oil can range significantly depending on growing conditions.

Safflower

Safflower was originally domesticated for its flowers: red carthamin dye was extracted for coloring food and cloth. Early cultivars were unsuitable for commercial development due to low oil content of ~30%. Breeding programs have since increased oil contents and altered the fatty acid profiles to take it from an industrial product to the edible oil market with modern cultivars containing 34% or more oil. Traditional high linoleic types contain ~68–83% linoleic acid and 8–22% oleic acid (Table 2). Through plant breeding, high oleic levels (70–84%) have been achieved. Due to the wide range of environmental conditions from countries as diverse as Australia, India, and China, fatty acids may vary considerably. The meal from safflower seed is also valued as a stock feed. The protein content of the meal remains relatively low in relation to other oilseeds at only 23%.

Mustard Seed

Typically mustard oil is high in erucic acid (20–50%) and the meal is high in glucosinolate compounds (50–150 μM g^{-1}), providing pungency to mustard for condiments but reducing the palatability of the meal for stock feed. With plant breeding, very low levels of erucic acid have been achieved and current aims are to develop cultivars that are more closely related to low erucic rapeseed cultivars, with increased oleic acid content.

Production and Trade

For the purpose of this article, fruit oils will not be discussed although it is significant. Palm oil fruit (from which comes the name palmitic acid) production in 2002 exceeded 136 Mt, second only to soybean. Oilseed yields from 1982 to 2002 are shown in Figure 1 and the area grown and yields of the various crops in 2001 and 2002 in Table 2.

Soybean

The global oilseed market is dominated by soybean with a total of ~180 Mt produced in 2002, making up almost 50% of the total oilseed production (Table 3). The United States of America produced 40%, with Brazil (23%), Argentina (17%), and China (9%) also producing significant amounts. Not unexpectedly, the United States is the largest exporter followed by Brazil and Argentina.

Cotton

Production of cotton in the last 20 years has gradually increased (Figure 1) with the result that cottonseed is the second largest oilseed crop despite its major purpose for textile use. China is the largest producer, with ~15 Mt per annum, together with the United States, India, and Pakistan. Australia is the leading exporter of cottonseed while Mexico, Spain, Japan, Italy, Korea, and United States are large importers.

Peanuts

A global peanut production of 35 Mt is led by China (14 Mt) with India (19%), Nigeria (8%), the United States (5%), and Indonesia (3%) also being significant producers.

Rapeseed

Rapeseed is currently rated in fifth position in world production of oilseeds with 33 Mt produced in 2002. There has been a continual decline from 1999 to 2002 (Figure 1) due partly to environmental conditions in leading producer countries. China is the largest producer of rapeseed with nearly one-third of the world production with India, Germany, France, and Canada also being major producers. Canada is the major exporter of rapeseed (canola) with exports of nearly 4 Mt in 2001, while France and Australia exported

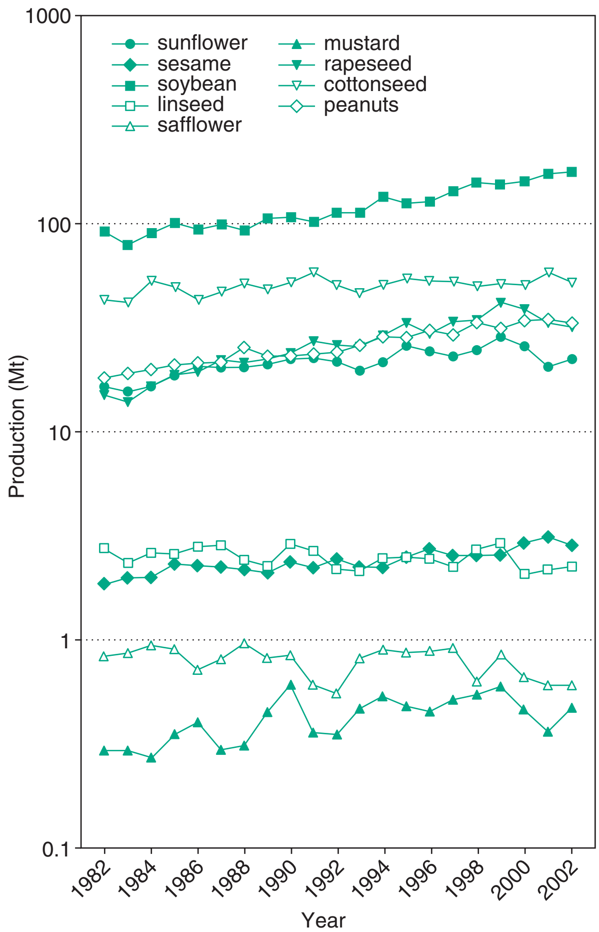

Figure 1 Global production of major oilseed crops ($\log_{10}$) from 1982 to 2002 in million tons (Mt). (Adapted from Food and Agricultural Organization of the United Nations Statistics.)

Table 3 World production of the major oilseed crops for 2001 and 2002

	Area harvested (Mha)		*Production (Mt)*	
	2001	*2002*	*2001*	*2002*
Soybeans	76	79	177	180
Cottonseed	34	32	61	54
Groundnuts	25	26	36	35
Rapeseed	22	23	34	33
Sunflower seed	18	20	21	23
Sesame seed	8	7	3	3
Linseed	3	3	2	2
Safflower seed	0.9	0.8	0.6	0.6
Mustard seed	0.5	0.6	0.4	0.5

Adapted from Food and Agricultural Organization of the United Nations Statistics.

nearly 1.5 Mt each. Japan is the biggest importer of rapeseed (canola) importing over 2 Mt in 2001, with China (1.7 Mt), and Mexico (0.9 Mt) also being major importers.

Sunflower

Sunflower production has increased dramatically in the period between 1982 and 2002, from 16 Mt toward 25 Mt (Figure 1). Argentina has been the major producer of sunflower seed in recent years with 17% of the total global production. Ukraine was the major exporter in 2002 with 584 000 T. Other exporters included France, Russia, Hungary, USA, and Romania. Major importers include Netherlands, Spain, Germany, Turkey, Italy, and Portugal.

Sesame

World production of sesame seed is increasing, from 2–3 Mt between 1982 to 3.17 Mt in 2001. All but a small part of total world production is from developing countries including India, Sudan, Myanmar, and China. India and Sudan are the largest exporters of sesame. In 2001, Japan imported 148 000 t. Other major importers were Korea, Egypt, USA, and China.

Linseed

World production of linseed has shown a gradual decline since the 1980s despite a peak in 1999 of almost 3 Mt (Figure 1). The total production of 2.21 Mt in 2001 was the lowest level of production in the previous forty years. The major producers of linseed are Canada, China, USA, and India. Canada is the major exporter with over 600 000 T exported in 2001.

Safflower

Production of safflower has also fallen in the 1980s from ~900 000 t in 1985 to 600 000 t in 2002 (Figure 1). This may reflect the increased demand for monounsaturated oil in place of polyunsaturated oils. The major safflower producing countries are India, USA, and Mexico. The USA (21 812 t) and Australia (13 660 t) accounted for 72% of the world exports. Japan is a major importer.

Mustard

There has been a gradual increase in world production of mustard since the 1980s (Figure 1) from ~360 000 t in 2001 to 500 000 t in 2002. Major producers include Nepal, Canada, and Russia. In 2001, Canada exported 152 000 t of mustard while the Czech Republic, Germany, Russia, and Hungary were also significant exporters. Bangladesh was the major importer in 2001.

Future Developments

Oilseeds play an increasingly important role in society, both as an edible food product and for industrial uses. The benefits include the valuable oil component and the secondary but also useful meal, which provides a high energy and nutritionally important food. Breeders have been able to optimize the characteristics of many of these crops to achieve higher levels of production and to alter the products to suit specific requirements. These changes include improvements in nutritional value, particularly with changes in fatty acid profiles and the reduction in antinutritional components. Undoubtedly the biggest changes will come in the future from genetic modification in which long term breeding programs can be dramatically reduced to relatively short periods of time. Traditional, breeding techniques rely on natural variability in plant populations to achieve change. Genetic engineering can create new products previously out of the reach of established breeding techniques. Engineering plants for specific aims or more suitable to environmental conditions can increase production. Nutritionally, fatty acid profiles can be dramatically altered to reduce saturated and trans fatty acids and simultaneously improve oxidative stability. Vegetable oils are already being substituted, in many instances, for less environmentally friendly petroleum products. The major competition to oilseed crops in the future will only be from the ever-growing range of additional oilseed types.

ORGANIC GROWING OF GRAINS

P Gélinas, Food Research and Development Centre, Saint-Hyacinthe, QC, Canada
C David, ISARA Lyon, Lyon, France

Introduction

Organically grown foods are also called ecologically or biologically grown foods. Organic agriculture has become more popular over the years, being practiced in ~1–5% of farmed land of most countries. Organic agriculture is an alternative to the striking increase of synthetic fertilizers and pesticide, which has become necessary to maintain high-productivity crops even if it leads to environment impacts (i.e., water degradation). This alternative agricultural method represents a viable solution especially well suited for constrained and low-input conditions (i.e., climate, regulation). Nonetheless, it cannot be assured that organically grown foods are safer, healthier, or more nutritive than conventionally grown produce. However, organically grown cereal crops might contribute to human health, for example, because it does not spread toxic pesticides in the environment. This article describes organic growing of grains and its regulations. Potential advantages and limits of organic growing of grains are also presented.

Definition

Contrary to conventional agricultural practice, the concept of organically grown foods is an ethical or holistic concept based on naturalness, which involves:

1. the absence of synthetic inorganic chemicals (laboratory-made) for growing and processing crops, like fertilizers, pesticides or insecticides;
2. an agro-ecological, broad, and long-term approach throughout the food chain, including care for soil fertility, recycling of agricultural materials from in-site or community, energy preservation, stimulating the self-regulating capacity of the agro-ecosystem and care for water, soil, and air quality preservation; concepts such as genetically-modified organisms (for seeds and others) and irradiation are not acceptable, and
3. the integrity of living nature as a whole, not strictly focused on crop production but also on animal welfare, environment, and social impact; for example, avoidance of any process or practice that might endanger the health of agricultural workers and consumers, including minimal food processing.

A key issue in the overall sustainability of the organic farming systems, compared to nonorganic, is the financial viability. On arable systems, the financial situation is critical during conversion while specific

machinery is required, yields fall and output prices are maintained without premium. Such system requires high selling prices and strong processing and marketing network. By definition, organic agriculture would suit better for locally-grown foods, considering the potentially negative impact of transportation on the environment.

In organic agriculture, the fertility and biological activity of the soil should be maintained or increased by (1) the cultivation of legumes, green manures, or deep-rooting plants in a multi-annual rotation program and/or (2) the incorporation into the soil of organic material, composted or not, from material produced under the regulations. Furthermore, organic fertilizers may only be applied if adequate nutrition of the rotating crop or soil conditioning cannot be ensured by other methods.

Weeds are often mentioned as the most significant problem in organic agriculture. Because no herbicides are allowed, the emphasis is on prevention and control technology. Preventive measures include: reduction of the supply of weed seeds and the multiplication of weeds and destruction of weeds before the crop is sown. Measures can be taken: (1) at the farm level through crop rotation and intercropping systems, (2) at the crop level by mechanical control, and (3) at the variety level by selecting genotype for competitiveness through plant architecture, rapid juvenile growth, deep rooting, and allelopathic exudates.

Pest and disease control is not performed with synthetic pesticides. Most soil-borne pests and diseases can be controlled by stimulating biodiversity in and above the soil, by good soil management, and by choosing site-specific crops through balanced rotation and selection of resistant crop varieties.

Regulations

Organic foods cannot be distinguished from nonorganic foods, even if analyzed for pesticides or nutritional content. Especially because premium price is paid for organic crops and foods, control is necessary to avoid fraud and determine which food is organic and which is not. Organically produced foods must meet international standards. For legally registered labeling, accredited certification agencies inspect farms and processing plants. Food production and process must be certified as organic, not the food itself. Principles are close to Hazard Analysis and Critical Control Point (HACCP), including regulations (on farmers' practices and food processing) and traceability. This means that detailed records of production techniques and inputs are subjected to audits from certification agencies.

Long before HACCP became a popular acronym, artisans of organic agriculture devised internal rules to ascertain that organic really meant organic. Within countries, legislations have been set up over the years, based on guidelines provided by Codex Alimentarius Commission created in 1962 to establish international norms for food on behalf of FAO (Food and Agriculture Organization) and WHO (World Health Organization). These norms are designed to favor food trade and protect human health, setting a minimum quality level for safety and trade. In 1999, this organization published international rules for production, processing, labeling, and commercialization of food produced according to organic agriculture. Production, processing, and commercialization (including labeling) of organic produces have been defined within the regulation. Depending on country or certifying group, the standards must be applied in full including withdrawal of all synthetic fertilizers and pesticides, after a transition period of 2 to 5 years before certifying organic products.

Worldwide, ISO Standard 65 has become the most accepted standard for organic certifiers. Within a country, control is made by representative organizations, which are, in some countries, recognized by government. Worldwide, the international market requires assurance of equivalency because definition of organic may slightly differ according to certification agency. In 1992, the International Federation of Organic Agriculture Movements (IFOAM) established the IFOAM Accreditation Program (IAP) to provide international equivalency of organic quality claims. The IFOAM is recognized as the leading group for organic agriculture organizations. A major inspiration for Codex standards, the IFOAM Basic Standards provide a framework for certification bodies and standard-setting organizations worldwide to develop their own certification standards (but cannot be used for certification on their own). Certification standards should take into account specific local conditions and provide more specific requirements than the IFOAM Basic Standards. Table 1 presents examples of approved inputs (fertilizers, soil conditioners, crop protectants, and growth regulators) for producing organic crops, based on IFOAM Basic Standards. This reflects the complexity of regulating the production of organically grown crops, a major task, which has been made through the years due to the commitment of organizations like IFOAM.

Food Processing Issues

Although not ideal, the same processing facility may generally be used to process organic and nonorganic grain. First batch in the morning should be reserved to

Table 1 Examples of approved inputs for organic crops production[a]

Substance	*Condition for use*
Acids (natural) (e.g., vinegar)	As crop protectant or growth regulator
Algal preparations (seaweeds and seaweeds preparations)	As crop protectant or growth regulator
Animal by-products (blood meal, meat meal, bone, bone meal, hoof and horn meal, feather meal, wool, fur, hair)	As fertilizer or soil conditioner
Animal preparations and oils	As crop protectant or growth regulator
Bacterial preparations (e.g., *Bacillus thurigiensis*)	As crop protectant or growth regulator
Basic slag	As fertilizer or soil conditioner
Beeswax	As crop protectant or growth regulator
Biodynamic preparations	As fertilizer, soil conditioner, crop protectant or growth regulator
By-products (biodegradable) from brewery, distillery, food, feed, oilseed or textile processing	As fertilizer or soil conditioner
Calcareous and magnesium amendments	As fertilizer or soil conditioner
Calcium chloride	As fertilizer or soil conditioner
Calcium hydroxide	As crop protectant or growth regulator
Carbon dioxide	As crop protectant or growth regulator
Chalk	As fertilizer or soil conditioner
Chitin nematicide (natural origin)	As crop protectant or growth regulator
Chloride of lime	As crop protectant or growth regulator
Clay (e.g., bentonite, perlite, vermiculite, zeolite)	As fertilizer, soil conditioner, crop protectant, or growth regulator
Compost from acceptable inputs (incl. spent mushroom waste, humus from worms and insects, urban composts from separated sources which are monitored for contamination)	As fertilizer or soil conditioner
Coffee grounds	As crop protectant or growth regulator
Copper salts (e.g., sulfate, hydroxide, oxychloride, octanoate)	As crop protectant or growth regulator; maximum 8 kg ha^{-1} per year (on a rolling average basis)
Corn gluten meal	For weed control
Crop and vegetable residues, including mulch, green manure, and straw	As fertilizer or soil conditioner
Dairy products (e.g., milk, casein)	As fertilizer, soil conditioner, crop protectant, or growth regulator
Diatomaceous earth	As crop protectant or growth regulator; also as pest and disease control
Epson salt (magnesium sulfate)	As fertilizer or soil conditioner
Ethanol (ethyl alcohol)	As crop protectant or growth regulator
Fish and fish products	As fertilizer or soil conditioner
Fumigants (ethylene oxide, methyl bromide, aluminum phosphide or other)	Forbidden
Fungal preparations	As crop protectant or growth regulator
Gelatin(e)	As crop protectant or growth regulator
GMO (genetically engineered organisms)	Forbidden
Guano (excrement of seabirds)	As fertilizer or soil conditioner
Gypsum (calcium sulfate)	As fertilizer or soil conditioner
Homeopathic and Ayurvedic preparations	As crop protectant or growth regulator
Insects (sterilized)	As crop protectant or growth regulator
Kieserite	As fertilizer or soil conditioner
Lecithin	As crop protectant or growth regulator
Limestone	As fertilizer or soil conditioner
Lime sulfur (calcium polysulfide)	As crop protectant or growth regulator
Magnesium rock, magnesium sulfate	As fertilizer or soil conditioner
Marl (maerl)	As fertilizer or soil conditioner
Manure (incl. farmyard slurry and urine; guano)	As fertilizer or soil conditioner; human excrements must not be applied on edible parts; no urea allowed
Microbiological preparations based on naturally occurring organisms	As fertilizer or soil conditioner
Mineral oil (light such as paraffin)	As crop protectant or growth regulator
Neem (*Azadirachta indica*)	As crop protectant or growth regulator
Parasites, predators and sterilized insects	As crop protectant or growth regulator
Peat	As fertilizer or soil conditioner; prohibited for soil conditioning, permitted for potting mixes
Pest and disease control	Only physical barriers, sound, ultra-sound, UV-light, traps (including pheromone traps and static bait traps), temperature control, controlled atmosphere, and diatomaceous earth

Table 1 Continued

Substance	*Condition for use*
Pheromones	As crop protectant or growth regulator; in traps and dispensers only
Plant preparations and extracts	As fertilizer, soil conditioner, crop protectant or growth regulator
Plant oils	As crop protectant or growth regulator
Plant based repellents	As crop protectant or growth regulator
Phosphates (natural)	As fertilizer or soil conditioner
Potassium (mineral, including sulfate of potash, muriate of potash, kainite, sylvanite, patentkali)	As fertilizer or soil conditioner; only those obtained by physical procedures, not enriched by chemical processes
Potassium bicarbonate	As crop protectant or growth regulator
Potassium permanganate	As crop protectant or growth regulator
Propolis	As crop protectant or growth regulator
Pyrethrum (*Chrysanthemum cinerariaefolium*)	As crop protectant or growth regulator; piperonyl butoxide is prohibited
Quassia (*Quassia amara*)	As crop protectant or growth regulator
Quicklime	As crop protectant or growth regulator
Rock (pulverized) and stone meal	As fertilizer or soil conditioner
Rotenone (*Derris elliptica, Lonchocarpus* spp., *Thephrosia* spp.)	As crop protectant or growth regulator
Ryania (*Ryania spaciosa*)	As crop protectant or growth regulator
Sabadilla	As crop protectant or growth regulator
Salt (sea) and salty water	As crop protectant or growth regulator
Seeds (organic, if available)	Only if nontreated with forbidden pesticides
Sewage sludge (municipal)	Forbidden
Silicates (e.g., sodium silicate, quartz)	As crop protectant or growth regulator
Soap (soft)	As crop protectant or growth regulator
Sodium bicarbonate (soda)	As crop protectant, growth regulator, crop protectant or growth regulator
Sugar beet lime	As fertilizer or soil conditioner
Sulfur	As fertilizer, soil conditioner, crop protectant or growth regulator
Sulfur dioxide	As crop protectant or growth regulator
Tobacco tea	As crop protectant or growth regulator; pure nicotin is forbidden
Trace elements (boron, copper, iron, manganese, molybdenum, zinc)	As fertilizer or soil conditioner
Vermicastings	As fertilizer or soil conditioner
Viral preparations (e.g., granulosis virus)	As crop protectant or growth regulator
Wood and wood by-products (ash, bark, charcoal, sawdust, shavings)	As fertilizer or soil conditioner

[a]Based on IFOAM Basic Standards for Organic Production and Processing (2002).

organic grain. Thorough cleaning must be used between transitions, leaving a transition period. In general, certified organic foods must be made with a minimum of 95% of organic ingredients (by weight), without considering water and salt. So-called organic foods may then be prepared with 5% of nonorganic ingredients, based on total weight of ingredients except water and salt. A major issue among organic certification groups is the list of approved ingredients and processing aids of nonorganic or synthetic origin. Table 2 presents a list of nonorganic ingredients and processing aids, permitted in organic foods.

Potential Advantages

1. *Alternative agriculture is adapted to low-input and constrained conditions*. Organic agriculture tends to limit soil erosion, compaction, or degradation by using crop diversity. It also limits the use of inputs like mineral fertilizers and synthetic pesticides.
2. *Small is beautiful*. Organic agriculture is a way to say that more modern and bigger is not necessarily better. For developing countries such as Cuba, organic agriculture is a way to seek independence over imported pesticides and mass monoculture of export crops requested by rich countries. Otherwise, the economy of developed countries is too often severely dependent upon international markets. For example, organic agriculture is adapted to family farming by increasing profitability per unit. In brief, organic crops cost less to produce (no expensive chemical fertilizers and pesticides, substituted by manure), have lower yields (25–35% less for grains), but get higher price (30–100% compared to nonorganic crops, sometimes more).

Table 2 Nonorganic ingredients (I), additives (A), and processing aids (P) approved in organic foods[a]

	Ingredient (I), additive (A), or processing aid (P)[b]	*Restriction*[c]
I	Acorns (*Quercus* spp.)	Only if unprocessed and not produced in sufficient quantity in EU (only in EU Regulation)
P	Activated carbon (charcoal)	Not in US Regulation (status pending, only as filtering aid)
A	**Agar (agar-agar)** (generally used as gelling agent)	
I	Algae, including seaweeds	Only if unprocessed and not produced in sufficient quantity in EU (only in EU Regulation)
A	Alginic acid	
A	Amino acids and nitrogen compounds	When required by legislation (only in EU Regulation)
A	**Ammonium carbonate (bicarbonate)**	Only as a leavening agent
A	Ammonium phosphates (incl. monoammonium phosphate, diammonium phosphate, phosphate dibasic or monobasic)	Only in wine (max. 0.3 mg l^{-l}) (only in IFOAM)
A	Ammonium sulfate	Only in wine (max. 0.3 mg l^{-l}) (only in IFOAM)
I	Aquatic organisms	Only if not from aquaculture and if not produced in sufficient quantity in EU (only in EU Regulation)
IA	**Arabic gum (gum arabic)** (generally used as gelling agent)	Only for milk products, fat products, confectionary, sweets, eggs (IFOAM and Codex); only if nonsynthetic and water extracted (US)
A	Argon	Not in US Regulation
A	**Ascorbic acid** (generally used as dough oxidation agent)	Synthetic form acceptable only if not available in natural form (Codex)
AP	**Bacterial starters (incl. dairy cultures)**	Only if not from GMO (product of rDNA technology)
P	Bark, preparation of	Only for sugar (IFOAM)
P	Beeswax	Not in US Regulation (pending); as releasing agent (Codex)
P	Bentonite	Only for fruits and vegetable products (IFOAM); only if nonsynthetic (US)
AP	**Calcium carbonate** (generally used as buffer in yeast foods)	Except in coloring (EU); only if nonsynthetic (US)
AP	Calcium chloride	Only in milk products, fat products, fruits and vegetables, and soybean products (Codex); only as coagulation agent (Codex and EU); only if nonsynthetic (US)
A	Calcium citrate	
AP	Calcium hydroxide	Only for maize tortilla flour and as processing aid for sugar (IFOAM)
A	**Calcium phosphate (monobasic, dibasic, tribasic)**	Uses discussed include baking powder, fortification, for yeast growth, and as a firming agent for yogurt (US); only monocalcium phosphate specified for IFOAM, Codex, and EU
AP	**Calcium sulfate** (generally used as dough firming agent)	Only for soybean products, cakes and biscuits, confectionery and bakers' yeast (IFOAM and Codex); only as carrier or coagulation agent (Codex and EU); only if nonsynthetic (US);
AP	**Carbon dioxide** (generally used as preservative agent in controlled atmosphere)	
P	Carnauba wax	Only as releasing agent (Codex)
IA	**Carob bean gum (locust bean gum)** (generally used as stabilizing or gelling agent)	Only if nonsynthetic and water extracted (US)
A	**Carrageenan (carrageen)** (generally used as stabilizing or gelling agent)	Only if nonsynthetic (US)
P	Casein	Not in US Regulation; only for wine (IFOAM)
P	Chlorine; calcium hypochlorite; chlorine dioxide; sodium hypochlorite	Only in US Regulation, for disinfecting and sanitizing food contact surfaces
A	Cellulose	Only in US Regulation for use in regenerative casings as an anticaking agent (nonchlorine bleached) and filtering acid
AP	Citric acid	Only if produced by microbial fermentation of carbohydrate substances (US); only for fruits and vegetable products, and pH adjustment (Codex); only for oil production and hydrolysis of starch (EU)
I	Cola nuts (*Cola acuminate*)	Only if unprocessed and not produced in sufficient quantity in EU (only in EU Regulation)
A	**Coloring agent** (color)	Only if not a synthetic substance primarily judged as being unnatural or as a “new construction” of food compounds; only if not produced by genetic engineering

Table 2 Continued

Ingredient (I), additive (A), or processing aid (P)[b]		Restriction[c]
I	**Cornstarch (native)**	Only in US Regulation (only if nonsynthetic)
AP	Cultures, dairy	Considered as bacterial starters; only if not from GMO (product of rDNA technology)
A	**L-cysteine** (generally used as dough conditioner; reducing agent)	Prohibited
P	Diatomaceous earth	Only for sweeteners and wine (IFOAM); only if nonsynthetic and as food filtering aid (US)
P	Egg white albumen (albumin)	Not in US Regulation; only for wine (IFOAM)
AP	**Enzymes**	Only if derived from edible, nontoxic plants, nonpathogenic fungi, or nonpathogenic bacteria; only if not from GMO; only if nonsynthetic (US); US Regulation also includes the following animal-derived enzymes: rennet-animals derived, catalase-bovine liver, animal lipase, pancreatin, pepsin, and trypsin (only in US Regulation)
P	Ethanol	Only as solvent (Codex and EU); not in US Regulation
P	Ethylene	Only for postharvest ripening of tropical fruit (US only)
P	Extraction	Only with water, ethanol, plant and animal oils, vinegar, carbon dioxide, or nitrogen (IFOAM)
I	Fats and oils (other than cocoa, coconut, olive, sunflower, palm, rape, safflower, sesame, or soya)	Only if not produced in sufficient quantity in EU (only in EU Regulation)
A	Ferrous sulfate (iron)	Only in US Regulation, for food fortification; see minerals
P	Filtration	Only if not with asbestos or with technique that chemically react or modify food on a molecular basis (IFOAM)
A	**Flavoring agent or extract (essential or volatile oil)**	Only if not a synthetic or unnatural substance; only if not produced by genetic engineering; only if not produced by nonsynthetic solvents, carriers or preservatives such as oil, water, ethanol, carbon dioxide and mechanical and physical processes (US)
I	**Fructose (from cereals and tubers)**	Only if not produced in sufficient quantity in EU (only in EU Regulation)
P	**Gas (incl. carbon dioxide, oxygen, and nitrogen)**	Permitted for controlled atmosphere (IFOAM)
P	Gelatin(e)	Only for wine, fruit, and vegetables (IFOAM); not in US Regulation (pending)
A	Glucono delta-lactone	Only if nonsynthetic and not produced by the oxidation of D-glucose with bromine water (only in US Regulation)
A	**Glycerol, glycerine**	Only from plant extract (EU); only if produced by hydrolysis of fats and oils (US)
AIP	GMO (from genetically modified ingredients)	Forbidden
I	Gooseberries (*Ribes uva-crispa*)	Only if unprocessed and not produced in sufficient quantity in EU (only in EU Regulation)
IA	**Guar gum** (generally used as gelling or stabilizing agent)	Only if nonsynthetic and water extracted (US)
P	Hazelnut shells	Not in IFOAM or US Regulation
I	Horseradish seeds (*Armoracia rusticana*)	Only if unprocessed and not produced in sufficient quantity in EU (only in EU Regulation)
P	Hydrogen peroxide	Only in US Regulation
P	Irradiation (ionizing radiation)	Prohibited
P	Isinglass	Only for wine (IFOAM); not in US Regulation
P	Isopropanol (propan-2-ol)	Only in sugar crystallization, until 31.12. 2006 (only in EU Regulation)
P	Kaolin	Only if nonsynthetic (US)
A	**Karaya gum** (generally used as gelling or stabilizing agent)	Not in IFOAM or US Regulation
A	Kelp	Only if nonsynthetic and for use as a thickener and dietary supplement (only in US Regulation)
A	Kirsch (from fruits and natural flavorings)	Only if not produced in sufficient quantity in EU (only in EU Regulation)
AP	**Lactic acid**	Only in fermented vegetable products (Codex); only if nonsynthetic and not derived from microorganisms that are products of recombinant DNA technology (US)

Table 2 Continued

Ingredient (I), additive (A), or processing aid (P)[b]		*Restriction*[c]
IAP	**Lecithin**	Only if unbleached and obtained without organic solvents (Codex); bleached and unbleached forms accepted in US Regulation
I	Lesser galanga (*Alpinia officinarum*)	Only if unprocessed and not produced in sufficient quantity in EU (only in EU Regulation)
IA	**Locust bean gum (carob bean gum)** (generally used as stabilizing or gelling agent)	Only if nonsynthetic and water extracted (US)
IA	Magnesium carbonate (generally used as drying and anticaking agent)	Only if nonsynthetic (US); only in agricultural products labeled "made with organic (specified ingredients or food groups)," prohibited if labeled "organic" (US)
AP	**Magnesium chloride (or nigari)**	Only for soybean products (IFOAM and Codex); only as coagulation agent (EU and Codex); only if derived from seawater (US)
A	Magnesium silicate (generally used as anticaking agent for salt)	Forbidden
A	Magnesium stearate	Only in US Regulation, only in agricultural products labeled "made with organic (specified ingredients or food groups)," prohibited if labeled "organic" (US)
A	Magnesium sulfate	Only in US Regulation; only if nonsynthetic (US)
A	Malic acid	Only in Codex
A	**Malted barley**	Only from an organic source
A	Minerals and vitamins (nutrients)	When required by legislation
A	**Mono-calcium phosphate**	Only for "raising flour" (IFOAM); raising agent for self raising flour (EU); for US, see calcium phosphate
P	Mono- and diglycerides	Only in US Regulation (only for drum drying of food)
A	Nisin	Prohibited
AP	Nitrogen	Only nonsynthetic and oil-free grades (US)
AP	Oxygen	Only nonsynthetic and oil-free grades (US)
P	Ozone	Only in US Regulation
I	Passion fruit or maracujas (*Passiflora edulis*)	Only if unprocessed and not produced in sufficient quantity in EU (only in EU Regulation)
I	Pea protein (*Pisum* spp.)	Only if not produced in sufficient quantity in EU (only in EU Regulation)
IA	**Pectin (unmodified)**	Nonsynthetic (high-methoxy) and synthetic (low-methoxy) sources allowed (US)
I	Pepper (Peruvian) (*Schinus molle* L.)	Only if unprocessed and not produced in sufficient quantity in EU (only in EU Regulation)
P	Perlite	Only if nonsynthetic and for use as filter aid in food processing (US)
P	Phosphoric acid	Only in US Regulation; only for cleaning food-contact surfaces and equipment (US)
A	Potassium alginate	Not in EU Regulation
AP	**Potassium carbonate (bicarbonate)** (generally used in baking powder)	Only in cereals, cakes, biscuits, and confectionary (IFOAM); only for drying of grape raisins and sugar production (Codex and EU)
A	Potassium chloride	Equivalent to sodium chloride and for food processing (EU); only in canned or frozen fruits and vegetables, vegetable sauces; for ketchup and mustard (Codex); only if nonsynthetic (US)
A	Potassium citrate	Not in EU Regulation
P	Potassium hydroxide	Prohibited for lye peeling of fruits and vegetables except for peeling peaches during the individually quick frozen (IQF) production (US); only for pH adjustment for sugar processing (Codex); not in IFOAM and EU Regulation
A	Potassium iodide (generally used as dietary source of iodine for salt)	Only in US Regulation, both synthetic and nonsynthetic allowed; if a synthetic source is used, only in agricultural products labeled "made with organic (specified ingredients or food groups)," prohibited if labeled "organic"
A	Potassium metabisulfite	Only for wine (only in IFOAM)
A	**Potassium phosphate (monobasic potassium phosphate; potassium biphosphate)** (generally used in baking powder)	Only in US Regulation, only in agricultural products labeled "made with organic (specified ingredients or food groups)," forbidden if labeled "organic" (US)

Table 2 Continued

	Ingredient (I), additive (A), or processing aid (P)[b]	*Restriction*[c]
AP	**Potassium tartrate; potassium acid tartrate (also called cream of tartar)** (generally used in baking powder)	Only if made from tartaric acid (US); only for cereals, cakes, and confectionery (Codex)
I	Rasberries (*Rubus ideaeus*)	Only if dried and unprocessed, and not produced in sufficient quantity in EU (only in EU Regulation)
I	Red currants (*Ribes rudrum*)	Only if dried and unprocessed and not produced in sufficient quantity in EU (only in EU Regulation)
P	Rice meal	Not in IFOAM or US Regulation
I	Rice paper	Only if not produced in sufficient quantity in EU (only in EU Regulation)
I	Rum	Only from cane sugar juice and if not produced in sufficient quantity in EU (only in EU Regulation)
I	Safflower flowers (*Carthamus tinctorius*)	Only if unprocessed and not produced in sufficient quantity in EU (only in EU Regulation)
I	**Salt (sodium chloride)**	Not included in the percentage calculation of organic ingredients; equivalent to potassium chloride (EU)
P	Silicon dioxide (amorphous)	Only as anticaking agent for herbs and spices (EU); only for wine, fruit, and vegetable processing (IFOAM); only as gel or colloidal solution (Codex)
A	Sodium alginate	
AP	**Sodium carbonate (or bicarbonate)** (generally used in baking powder)	Only in sugar production (EU and Codex); only if nonsynthetic (US)
A	Sodium citrate	Not in EU Regulation
AP	**Sodium hydroxide**	Only for the surface treatment of traditional bakery products (IFOAM and EU); only for cereal products (Codex); only for sugar production and oil production from rape seed (*Brassica* spp.) (EU); prohibited for lye peeling of fruits and vegetables (US)
A	Sodium phosphates	Only in dairy foods (only in US Regulation)
AP	**Sodium tartrate** (generally used as stabilizing or gelling agent)	Not in US Regulation; only for cakes and confectionery (Codex)
A	**Sorbic acid** (generally used as preservative agent)	Prohibited
I	**Starch (from rice and waxy maize)**	Only if not chemically modified and not produced in sufficient quantity in EU (only in EU Regulation)
A	Sulfur dioxide	Only for wine (IFOAM; Codex); only in wine labeled “made with organic grapes,” provided that total sulfite concentration does not exceed 100 ppm (US); not in EU Regulation
P	Sulfuric acid	Only for pH adjustment of extraction water in sugar production (Codex); only for sugar production (EU); not in US Regulation
P	Talc	Not in US Regulation
P	Tannic acid, tannin	Only as filtration aid for wine; not in US Regulation
AP	Tartaric acid	Only for wine (IFOAM)
A	Tocopherols (mixed natural concentrates)	Allowed if derived from vegetable oil when rosemary extracts are not a suitable alternative (US); only as antioxidant in fats and oils (EU)
A	Tragacanth gum	Not in US Regulation
I	Unleavened bread paper	Only if not produced in sufficient quantity in EU (only in EU Regulation)
P	Vegetable oil	Only as greasing, releasing, or antifoaming agent
A	Vitamins and minerals (nutrients)	When required by legislation
IP	Water (drinking)	Not included in the percentage calculation of organic ingredients
I	Watercress herb (*Nasturtium officinale*)	Only if unprocessed and not produced in sufficient quantity in EU (only in EU Regulation)
P	Waxes, plant derived (beeswax, Carnauba wax)	Only as releasing agents (Codex and EU); beeswax not in US Regulation (pending)
I	Whey powder (*herasuola*)	Only if not produced in sufficient quantity in EU (only in EU Regulation)
P	Wood resin	Only in US Regulation

Table 2 Continued

Ingredient (I), additive (A), or processing aid (P)[b]		Restriction[c]
A	**Xanthan gum** (generally used as stabilizing or gelling agent)	Only for fat, fruit and vegetable products, cakes and biscuits (IFOAM; Codex); only for salads (Codex)
AP	**Yeast (autolysate, bakers, brewers, nutritional, smoked)**	Only if nonsynthetic and not grown on petrochemical substance and sulfite waste liquor; only if not from genetic engineering; nonsynthetic smoke flavoring process must be documented (US)

[a] Where the substances listed in this annex can be found in nature, natural sources are preferred. Substances of certified organic origin are also preferred.
[b] Products with bold character are most likely to be found in grain-based foods. According to IFOAM (2002), *processing aids* are any substance or material, not including apparatus or utensils, and not consumed as a food ingredient by itself, intentionally used in the processing of raw materials, foods or its ingredients, to fulfill a certain technical purpose during treatment or processing and which may result in the non-intentional, but unavoidable presence of residues or derivatives in the final product; some specific processes have also been mentioned as processing aids. According to Codex (2001), *ingredient* means any substance, including a food additive, used in the manufacture or preparation of a food and present in the final product although possibly in a modified form. For the sake of clarity, ingredients normally used at low concentrations have been classed as *additives*.
[c] Codex: Based on Guidelines for the production, processing, marketing, and labeling of organically produced foods. Codex Alimentarius Commission and the FAO/WHO Food Standards Programme (2001; www.codexalimentarius.net). US: Based on Regulation of the United States Department of Agriculture (The National Organic Program) (as of 3 November 2003), according to www.ams.usda.gov.

Large milling and baking plants are usually absent from the organic market because they are highly automated and require significant volumes to be cost-effective.

3. *Road to alternative cereals*. A niche market, organic cereal foods offer interesting possibilities to develop or introduce new cereal-based foods such as those made from nontraditional or specialty grains such as ancient wheat (spelt or khorasan). Niche markets are then available through organic grains, which give access to such specialty cereals containing much fiber and often having special flavors. Some people also switch to nontraditional cereals because they are sensitive (but not necessarily allergic) to standard cereal foods from wheat.

   Organic agriculture is a way of life for some persons. For others, it is a way to diversify their foods. Several people are also looking for something else; this might be translated into an opposition to the leveling of the taste and appearance of foods. This is contrary to the idea of food quality as seen by food industry: nonuniformity. For several people, the popularity of organic cereals is closely linked to nostalgia of the past, especially taste. A question of lifestyle, some want to produce these foods themselves; others are willing to pay more to get foods with specific qualities they want or believe it has. And these people are willing to pay more for this insurance on food.
4. *A question of confidence*. Confidence of customers in food has been shaken by food crisis as Mad Cow disease. Justified or not, lack of confidence in food is one of the reasons for choosing organic foods. Internationalization of decisions on food production may also be seen as a threat, enticing some people to come back to alternative agricultural and food consumption practices. Some references on organic foods state that they have a higher nutritive value than nonorganic foods. Others conclude that organic foods are potentially riskier considering that some of the most powerful poisons are of natural origin (mycotoxins). Also, organic foods could be related to a wish to avoid foods from genetically-engineered organisms, due to their potentially negative impact on environment.

Are organic foods much better both for health and earth? There is no guarantee that organic foods are safer, tastier, and more nutritive than nonorganic foods. In general, it is recognized that organic foods are likely to contain less residues of agricultural chemicals than nonorganic foods. However, this source of contamination is considered very low in any food. For the moment, health risks might be more important for growers themselves (plus their relatives and neighbors) who are in contact with concentrated pesticides than the public. Toxicity of agricultural practices remains a critical issue. Organic grain and foods growers banish the use of well-known toxicants such as concentrated chemical pesticides in the environment, with potentially questionable or not-so-sure long-term impact on human health.

Potential Limits

Most of the nontraditional cereals are more expensive than typical cereals partly because they are still marginal crops. This may limit accessibility of specific cereals, due to bad environmental conditions

especially if produced by few growers. More and more of these products are now available in North American and European supermarkets. In general, higher prices must compensate for lower yields so any possibility to improve yields will lower price and popularity of organic crops. Because yields of organic crops are generally lower than nonorganic, organic agriculture is unlikely to feed the world, especially developing countries. According to most scientific studies, foods from organic-grown crops (including grains) are not more nutritive than non-organic foods.

Future Prospects

It is expected that organic agriculture will remain popular for grain growers. For organic agriculture, specific grain varieties might be developed, especially those with long straw length, likely to limit growth of weeds through shading. Better understanding of organic grain growing will benefit from research as more scientists will become interested to this sector. On the long term, expansion of the organic grain market will be faced with identity problems. In essence, it is an ecological alternative to conventional agriculture (using synthetic inputs) but is perceived as a safer and more nutritive grain, without ecological significance for citizens. The question of the quality of organic grain-based foods also remains to be addressed, considering the minimum input from ingredients used in conventional foods. Because environment certainly has a major impact on human health, the organic way to grow grains is a nice alternative to conventional agriculture.

As mentioned, it is not expected that organic growing of grain will replace nonorganic agriculture. Up to now, this alternative agriculture is mainly a phenomenon associated with industrialized countries, especially Europe and America. Within less than 50 years, land surface devoted to organic agriculture has grown from literally nothing to a few percents.

At the turn of year 2000, large food manufacturers and distributors have now embarked the organic train. This is symptomatic of the attractiveness for safe, nutritive, flavorful, and guilty-free foods for which some consumers are ready to pay an "insurance premium." Will the popularity of organic foods only grow in the hands of large food consortiums? This is difficult to determine because the organic food market is still in transition. One sure bet is that the availability of organic foods in large supermarkets has given much credibility to organic agriculture in general. We may continue to see two markets for organic foods: one from mass and probably industrialized food sectors with limited potential for addressing rural priorities, and another for small-land or "terroir" tailored foods. Overall, the quality of these two types of organic foods might be different but they may well replace a significant part of the traditional but non-organic healthy foods. This popularity should slowly reduce prices and make these foods even more attractive to low-budget consumers. Nowadays, in Canada for example, it is very easy to get bread made from organic grain, with a special and appealing flavor and aroma due to the use of whole wheat or specialty grain. This appeal for new bread flavors and appearance is following the lasting interest for beer from micro-breweries since the 1980s. Around this time, many speculated that such special beer market would not survive long. Like specialty beer, organic growing of food and grain has probably given us another lesson: it is here to stay.

OVEN TECHNOLOGIES

C E Walker, Kansas State University, Manhattan, KS, USA

Introduction

Baking ovens were used far back into antiquity, well before recorded history. No one knows exactly when and where baking, and hence the oven, was developed. Most likely, it was a gradual process with baking tools and skills developed through a slow combination of serendipity and ingenuity (*see* **Bakeries. Milling and Baking, History**). The oven is the single most important, most expensive, and most complex piece of equipment used in bakeries. It limits the throughput, the variety, and the quality that the bakery can produce. It is also the least understood, most misadjusted, and most poorly maintained piece. It consumes the most energy and creates the most pollution, takes the most space, and generates the most controversy among its users. An oven cannot correct prior processing mistakes, but it can certainly limit everything done before. The success or failure of a baking venture is often determined by the oven, but the oven is sometimes the last item to be considered when a new bakery is being designed and equipped. Even though a well-designed and maintained oven will last for decades, its specifications often are reduced to "cost is the first consideration," rather than product suitability, lifetime utility, and maintenance costs.

Oven Classifications

Ovens today may be classified by several methods, as detailed below.

Scale (Includes Cost, Size, and Capacity)

The local "corner hot bread shop" or "in-store bake-off" will use small batch ovens. These may only operate a few hours per day, perhaps baking only a hundred loaves, and will almost be totally automatically controlled. They require very little skill to operate properly. The "baker" only needs to put the loaves (which may be frozen dough or even parbaked) into the oven and removes them when the buzzer sounds. Temperature, air circulation, and other settings are all carefully controlled by the manufacturer. Larger-scale institutional or small wholesale bakers are probably using rack or reel ovens, still manually batch loading them. They may bake a few hundred to a few thousand loaves per day. More judgment and skill is required on the part of the baker not only

because of the oven, but because the entire operation is probably a "scratch" bakery, preparing doughs and batters from individual ingredients, not from mixes or frozen items. Some of these bakers may be operating automated, thermal oil heated, deep hearth (setter) ovens. Finally, the large-scale high-speed plant bakeries baking 100 loaves per minute on each of several parallel lines will have highly automated continuous ovens in which molded dough pieces are automatically deposited into pans, proofed, loaded into a continuous oven, baked, de-panned, cooled, and sliced without human contact.

Products Being Baked

Except in very small shops, breads are baked in ovens that differ from sweet dough foods such as chemical- or yeast-leavened pastries. Cookies and crackers will be baked in a different design yet, and cakes and pies require still another design. While smaller bakers may use a "one-for-all and all-for-one" oven, by far the best results will be obtained using an oven designed for the specific baked food type.

Physical Arrangement

Different physical arrangements for ovens began with the descendents of the primitive beehive ovens as hearth or deck ovens, rotary hearth, rotary rack, reel, traveling tray ovens with single or multiple laps, and finally the long, continuous tunnel ovens used for crackers and cookies. Some of these designs will be described in more detail later in this article.

Heat Sources

Except in small primitive bakeries and by a few "boutique" bakers, wood is seldom used in ovens today. The energy source is usually refined petroleum, gas, or electricity. A few attempts have been made to use solar energy, but this is not yet a significant contributor except in a few isolated locations used by individual bakers living in very hot and sunny countries with a shortage of fossil fuels. Likewise, coal is seldom used because it is so dirty.

The fuel may be burnt directly in the baking chamber, though there is an increasingly popular trend toward using indirectly fired ovens in which the combustion chamber is kept separate. A relatively recent modification is to heat special high-temperature oil at some distance from the oven and then pump it to large horizontal heat exchanger plates in the baking chamber.

Within the oven, heat must travel in some fashion from the source to the raw dough. There are several mechanisms that accomplish this. Radiation, both thermal and electronic, is used, as is direct conduction between the hot oven surface and the dough. Likewise, convection (natural or forced) uses hot air to transport the heat. There are some other lesser known methods, such as direct ohmic resistance in which an electric current passes directly through the baking product, heating it throughout. Of course, there are ovens that use two or more of these forms simultaneously. When thermal sources are combined with electronic sources (microwave or radiofrequency (RF)), they are often called "hybrid" ovens. The following section presents a simplified description of the principal heat transfer modes.

Heat Transfer Mechanisms

"Heat" is energy in motion. A hot object transmits its energy to another when some of the thermal vibrations are transferred. The mechanisms for heat transfer are usually classified in three basic types, radiation, conduction, and convection, with some additional variations and combinations. These are described next.

Thermal Radiation

Radiant energy does not need a medium to carry it, as it falls in the electro-magnetic spectrum. Thermal radiation is energy that is transferred when the baking product can "see" the heat source, which is often incandescent although the most effective heating wavelengths are usually in the infrared (IR) region, invisible to the human eye. For example, electrical elements may glow "red hot," or gas flames may heat ceramic blocks to incandescence. By controlling the temperature and the nature of the radiator, it is possible to determine the wavelength at which the radiant energy is emitted.

Energy transfer by radiation can be expressed by a relatively simple equation. Note the importance of the temperature term, raised to the fourth power. If the absolute temperature in degrees kelvin (°C + 273.16) is doubled, the heat transfer rate will be 16 times as fast:

$$Q_R = e\sigma A\left(T_h^4 - T_c^4\right)\Delta\Theta \qquad [1]$$

where Q_R is the net radiant energy transferred, e the emissivity of the radiating body, varying between 0 and 1, σ the Stefan–Boltzmann constant for radiant energy, A the area to which heat is being transferred, T_h the absolute temperature of the hot, or emitting, body, T_c the absolute temperature of the cold, or absorbing, body, and $\Delta\Theta$ the time increment over which the radiation occurs.

Radiant energy is very effective for browning surfaces, but it does not penetrate very far below

the surface. Some large ovens have a "browning" section immediately before the discharge end with IR elements that can be used to control the final surface color. IR heaters are familiar as the deep red lights above restaurant serving counters, keeping food warm while it waits for delivery to the customer. Small "toaster" and "pizza" ovens sometimes use this principle. They are relatively cheap to construct and work well on relatively thin products such as biscuits. The principle is not satisfactory as the sole energy source for thicker objects such as pan bread loaves, because the surface heats very rapidly, browning quickly before the heat can penetrate to the interior and complete the baking process. Irregular surfaces are also difficult to bake with IR, because any exposed points burn before the rest is hot. Thermal radiation is a component in nearly all ovens, but is usually accompanied by conduction and convection.

Conduction

The higher the temperature of a substance is, the more rapidly its molecules vibrate, and the vibration may be passed by contact from one molecule to another. If a cold substance is in contact with a hot object, the molecular vibrations are passed from the hot to the cold substance and the "heat" is transferred. The more rapidly (the hotter) the source molecules vibrate and the better the contact between hot and cold bodies, the more efficiently the energy will be transferred. Metals are good thermal conductors and still air is a very poor conductor. Ceramics are intermediate. The ability of a material to transmit heat energy through it is called its thermal conductivity.

Heat transfer by conduction may also be described by a relatively simple equation involving the temperature difference between the donating and receiving objects. In this case though, unlike radiation, the temperatures are only raised to the first power, not the fourth, so the driving force from temperature is not as dramatic:

$$Q_c = \kappa A(T_h - T_c)\Delta\Theta/d \qquad [2]$$

where Q_c is the net heat transferred, κ the thermal conductivity coefficient, A the area across which heat is transferred, T_h the temperature of the hot or donating body, T_c the temperature of the cold or receiving body, $\Delta\Theta$ the time increment over which the heat transfer occurs, and d the distance, or thickness, through which the heat must migrate.

Most early baking used conduction to get the heat inside the food. Hot stones sitting in coals transferred their heat directly and rather rapidly to the dough placed on them. Even today, hearth breads are often placed directly upon the hot oven floor, perhaps separated slightly by a thin layer of bran or maize meal to keep loaves from sticking. The energy transfer is rapid and efficient so long as the bread makes good contact. Heat transfer between the dough and a pan can be improved by putting a thin layer of oil in the bottom before panning a pizza crust, for example. As a result the pizza may have almost a "fried" instead of a "baked" crust character.

Many baked foods such as biscuits (cookies and crackers) are baked upon continuous bands inside tunnel ovens. The direct gas flame heats the band and the small, thin biscuits are baked quickly, often in less than 3 min, because heat transfer is rapid. By preheating the oven band to an extra high temperature, the bottom of the dough piece is heated extremely hot, while the top is still relatively cool. The heat transfers so rapidly into the dough that small interior bubbles are generated by the rapid release of leavening and water as steam. The resulting dried product is very crisp yet very tender. Similarly, "flat breads" such as pita and tortillas are baked at even higher temperatures, up to 400°C for less than 1 min.

Conduction inside dough is usually slower than the rate at which heat can reach the surface. Calculating the heat transfer rate inside a baking food is very difficult because the heat transfer coefficient, κ, varies not only with the chemical nature of any substance (protein, starch, water, etc.) but also because as the product bakes, its structure and chemical composition change. The "κ" value will even be different in various parts of the food at the same time. The crust may be dry and hard with large air-filled pores. The resulting thermal conductivity is very low. On the other hand, raised dough with greater moisture will conduct heat more rapidly. This becomes more complicated as we consider convection and the "steam pipe" effect in the following section.

Convection

Convection heat transfer requires a moving fluid. Convection may be "natural," caused by air and steam circulation resulting from density differences. Hot gases expand, become less dense, and rise to the top, whereas the cooler gases settle to the bottom where they are reheated, resulting in vertical circulation inside the oven. Hot gases heat the baking dough by transferring energy across a boundary layer by conduction. The boundary layer is the relatively cool, moist, and dense layer surrounding the dough piece. Natural convection is present in most ovens, though it is not very efficient and heats rather unevenly. Fan-forced convection ovens operate more efficiently by circulating the hot gases more rapidly

and the hot gases are not limited to a vertical motion. A special form of forced convection, "impingement" directs jets of hot gases perpendicularly onto the baking food at high velocity, sweeping aside the boundary layer as well as bringing the hot gases there more rapidly (Figure 1).

The equation for heat transfer by conduction resembles the heat equations for the other two principal forms. Again, the difference in temperature between the heat source (circulating fluid in this case) and the baking product is the driving force. The rate is also controlled by the convective heat transfer coefficient. Remember that, like the radiation example, this equation only describes how the heat reaches the surface, not how fast it moves to the interior of the baking product:

$$Q_v = hA(T_h - T_c)\Delta\Theta \qquad [3]$$

where Q_v is the net heat transferred, h the convective heat transfer coefficient, A the the area across which heat is transferred, T_h the temperature of the hot or donating body, T_c the temperature of the cold or receiving body, and $\Delta\Theta$ the time increment over which the heat transfer occurs.

The convective heat transfer coefficient, h, is very difficult to predict based upon theoretical considerations, though many attempts have been made to do so. It is principally affected by the air velocity and flow pattern, but also by the temperature, pressure, and moisture content, all of which affect air density and viscosity, and hence control the properties of the stagnant boundary air layer that surrounds an object. Surface geometry also affects the convective heat transfer coefficient, especially for natural convection. For engineering scale-up purposes, it is more often satisfactory to determine the apparent convective heat transfer coefficient, h_a, experimentally. This can be done by measuring the rate of temperature rise of a standardized metal plate, usually aluminum, placed inside the oven.

Nearly all ovens will have some convection and it has been estimated that convection and radiation account for roughly equal contributions to the net heat transfer in conventional natural convection ovens. Many large commercial ovens have forced circulation by one means or another, not only increasing baking speed, but more importantly, improving baking uniformity. Likewise, institutional food service-type convection ovens are relatively common. They have a fan that circulates the air at rather high velocities and bake in less time with more uniformity.

The most dramatic use for forced convection is in the many tens of thousands of small units built for pizza restaurants since the mid-1970s. They force the circulating air through many small nozzles (~1.0–1.5 cm in diameter) at air velocities ~150–200 m s^{-1} (meters per second). Higher velocities are possible, but they sometimes levitate the ingredient toppings. By impinging the air jets perpendicularly at the surface, these ovens sweep away the dense, viscous boundary layer and bring heat closer and more rapidly to the baking pizzas. With jets both above and below, pizzas now go from totally raw to fully baked in 5–8 min as compared with the 20–30 min required when they were baked in deck ovens. The tremendous expansion in pizza outlets was only possible after impingement ovens were developed (Figure 2).

Similar principles have been incorporated into tube-impinged breakfast cereal toasters. They increase throughput, reduce breakage, and improve quality for ready-to-eat breakfast cereals (*see* **Cereals**: Breakfast Cereals for more information).

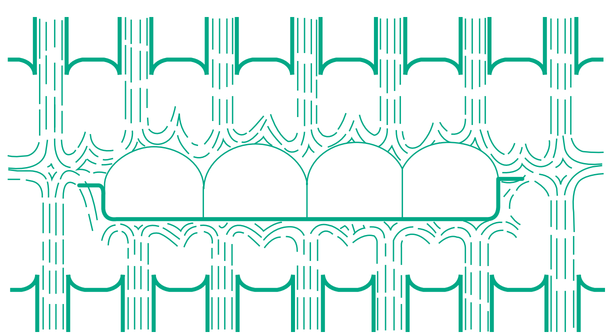

Figure 2 High-efficiency air impingement directs small jets from both above and below, at right angles to the product surface. (Reproduced with permission from Varilek P and Walker CE (1984) Baking and ovens: history of heat technology IV. *Bakers Digest* 58(2): 14.)

The Steam Pipe Effect

When engineers first began to study heat transfer in the new rapid-bake impingement ovens, they could not explain why the net heat transfer rate appeared to be higher than would be expected. Efficient convection would heat the surface rapidly, but the cold, moist interior (like in raw pizza dough) was thought to be limiting because it had a lower thermal conductivity. They eventually discovered that the improved heat transfer inside the products being baked with very high apparent convective heat transfer coefficients could be explained by an interesting mechanism. This works best on porous products with relatively high moisture contents.

Heat applied to a surface by the impingement process moves by conduction relatively rapidly across the thin solid wall of the "bubble" or cell. Moisture evaporates from the hot side and migrates as vapor across the cell and condenses onto the inner, cooler cell wall. The latent heat of vaporization then migrates across another thin cell wall and evaporates more moisture on the other side. The process continues until it eventually reaches the center where it meets a similar phenomenon approaching from the other side (Figure 3).

Not only does the heat move in, but there is also a net moisture migration to the center. The result is that in a loaf of bread fresh out of the oven, even though it has lost ~10% by weight during baking, and the outside may be quite dry and crisp, the loaf center actually has higher moisture content than the starting dough. The moisture redistributes rather quickly, and the starch and protein have been changed by the 95–98°C temperatures in the center, so the inside is cooked, not raw or dough like.

Oven Designs and Commercial Examples

Traveling Tray Bread Ovens

By around the year 1900, commercial baking had reached the point where the peel-hearth or deck and reel design ovens popular at the time could not keep up with demand. Tunnel ovens were designed in which pans entered at one end, traveled slowly through the entire length, and exited the other end. Limited automation was then practical, but the ovens were expensive and took a huge amount of floor space.

The next innovation was combining the tunnel oven design with an extension to the concept. In a reel oven, two large wheels rotate vertically inside the baking chamber, much like on an amusement park Ferris Wheel, with trays (instead of passenger seats) suspended between. Pans were placed on the trays and they revolved until the products were done. It was an important innovation, and reel ovens are still used in many smaller bakeries, because they are versatile and products requiring different baking times can be baked together (Figure 4). The traveling tray oven extended the oven from front to back by adding

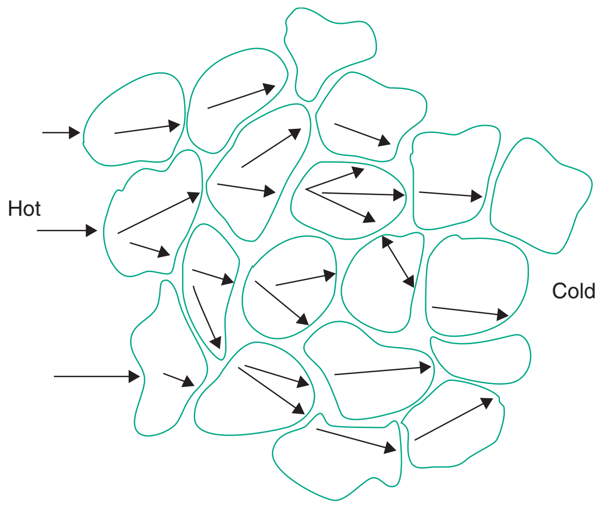

Figure 3 The "Steam Pipe Effect" can explain why heat transfer across a porous substance is more rapid than otherwise predicted, and how there is a net moisture migration toward the center. As heat moves through the cells, moisture simultaneously evaporates and recondenses, moving from the hot to the cold portions in the dough.

Figure 4 The reel oven was once very popular in wholesale bakeries and is still used in some retail and food service operations. (Courtesy of the Reed Oven Co., Kansas City, MO, USA.)

a second set of wheels and connecting them with heavy chains, to which trays were attached. Bread was loaded and unloaded through the same door. As their size grew, they eventually reached a length such that one pass took the entire baking cycle, so the batch oven evolved into a continuous oven, with products entering and leaving continually, never crossing paths with each other (Figure 5).

The floor space for these ovens was more efficient than the tunnel oven, because a complete lap involved two passes through the oven, front to back and back to front. Only limited baking zone control was possible though, as compared with the true tunnel oven in which product entered one end and exited the other. Some manufacturers added a second pass through the same baking chamber, creating the double-lap oven. In the USA in 1923, 93% of the industrial bread ovens were the manually peel-loaded, batch type. By 1929, as the tunnel and traveling tray ovens were introduced, the portion of peel ovens fell to ~50% (Figure 6).

Cracker Ovens in a Tunnel

By 1931, the single pass tunnel oven design was no longer used for bread but the traveling trays were replaced by a solid or very heavy mesh continuous band and adopted by biscuit and cracker bakers. Typical cracker tunnel ovens are now more than 1 m wide and 100 m or more in length, for a 3 min bake. This provides for tremendous capacities, e.g., 2000–3000 kg of product per hour. Their multiple zones provide the operator with great control over product quality. For example, they are often direct-gas fired with burners both below and above the band. The burners above the band, especially, may have IR radiating ceramic elements (Figure 7).

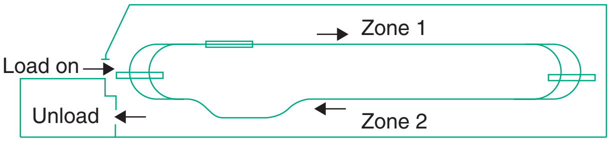

Figure 5 The single-lap traveling tray oven carries trays loaded with several pans of products through the oven in one pass. (Reproduced with permission from Pyler EJ (1988) *Baking Science and Technology*, 3rd edn., vol. II, p. 1188.)

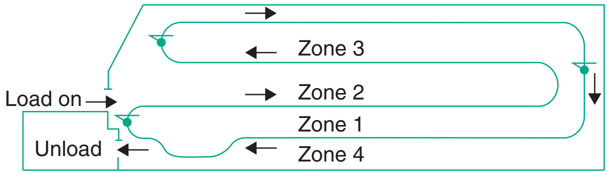

Figure 6 The double-lap traveling tray oven carries its trays through two passes of the heating chamber. (Reproduced with permission from Pyler EJ (1988) *Baking Science and Technology*, 3rd edn., vol. II, p. 1189.)

Few basic design innovations have been made in industrial-scale bakery ovens since the mid-twentieth century, although automation, energy conservation, and increasingly sophisticated controls have evolved substantially. At the smaller wholesale, retail, and restaurant/food service scale, however, many innovations have appeared, nearly totally replacing the earlier deck and, to a lesser extent, the reel designs in many markets.

Rotary Rack Ovens

Rotary hearth ovens provided advantages over the deck and peel designs, because each item was easier to access and could be put in and removed at a different time from the others. Their heavy, slow-moving, hearths were very stable and ideal for cakes and pies. In order to increase floor space efficiency, multiple decks (up to about five) were stacked. This design is currently in use in some retail and small wholesale bakeries. However, they are still slow and laborious to load and unload and require many manual transfers between forming, proofing, baking, and cooling.

An improved concept now used in many large retail and small wholesale bakeries was developed by rolling the entire rack of pans inside a large vertical cabinet oven. Products could be panned on plain or perforated trays, the rack rolled into the proofing cabinet, and when ready for baking, the entire load rolled onto the oven. Humidity could be introduced by injecting steam or by dripping water onto large metal balls stored in the wall, in the air path. Air is blown at high velocity from one side of the oven across the trays. In order to bake more uniformly, the air direction could reverse automatically, and, in the more popular current versions, the entire rack rotates during the total baking cycle. The rotary rack oven is probably the choice for most new institutional food service and retail bakeries, and sometimes they are installed in multiples for small wholesale operations, especially those that need to process a variety of products ranging from pastries and pies to bagels, as well as breads and rolls. The

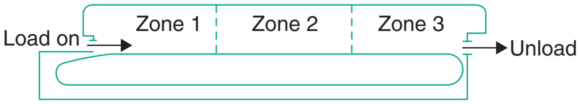

Figure 7 Band ovens with thin solid metal or heavy mesh baking bands are used principally for baking cookies and crackers. (Reproduced with permission from Pyler EJ (1988) *Baking Science and Technology*, 3rd edn., vol. II, p. 1190.)

ovens occupy a size and versatility niche where they are difficult to beat.

Impingement Ovens

The ancestors of the present-day ubiquitous impingement ovens owe their existence to attempts to cool radar tubes during the Second World War. It was discovered that if air was blown on the tubes through small nozzles, the heat transfer was more efficient and the tubes had longer life. In the early 1970s, a university food service operator asked the inventor of that cooling technology how to cook pizzas, rapidly expanding in popularity with college students, faster and with shorter lead time than possible in their deck ovens. The result was a series of small ovens that blew high velocity hot air through nozzles perpendicularly onto the pizza. Baking times dropped to well below 10 min, so the large pizza restaurant chains began to adopt the ovens. The original patented design used "fingers" extending from the air plenum on the side of the oven. The fingers were perforated with drawn nozzles below collimating plates and directed the air at the baking foods. The ovens were conveyorized with an open mesh and nozzles were placed both below and above the product. Belt speed determined bake time, reducing operator error.

Forced convection air impingement ovens today use small nozzle holes, short tubes, perforated plates, or narrow slits to blow air at high velocity perpendicularly onto the baking food. The air jets or curtains "sweep" aside the relatively cool, moist, viscous, dense boundary layer close to the product surface. The result is that the heat can reach the product more efficiently. The product can be baked in a shorter time, at a lower temperature, or both. This principle is especially effective with thin foods. Many consumers will be familiar with these ovens behind the counter in their local pizza restaurant (Figure 8).

Figure 8 High-speed air impingement ovens commonly bake pizzas in ~7 min. These rapidly replaced the slower deck oven design previously used. (Reproduced with permission from Middleby-Marshall Corp. "Press Kit" CD. ©2001.)

Other manufacturers produced competing equipment using tubes or slots, both of which had been used earlier in commercial equipment for other markets, to deliver the air at high velocity. Their uses expanded from the original pizza shops to encompass restaurants and food service on a larger scale. Casseroles, steaks, small bread loaves, cakes, and pies joined each other in the same oven. Even though the high air velocities result in rapid moisture evaporation, the residence time in the oven is reduced so much that products lose less moisture and generally have superior texture and increased shelf life.

Forced convection tends to provide very uniform heat, so the principle was applied to a large commercial scale pie oven. Highly automated, it could change fan speed and nozzle height "on the fly," permitting different products to be baked in the same oven at the same temperature, leaving only a short break between formula changes. By the mid-1990s, several large-scale tunnel ovens using the principle of high-velocity air impingement from slots or nozzles were being used to bake baking powder biscuits (resemble English scones), flat breads, and many other products on a large scale to meet the growing needs of demanding customers like fast-food chains.

Any savings in baking times, lower temperatures, and reduction in energy use vary with the nature of the product (thickness, water content, etc.) and with the nozzle design and locations, but most importantly with the air velocity. As a general rule, the product of "time" and "driving temperature" can be reduced to about one-half, where "driving temperature" = "oven temperature" – "product starting temperature." Although it is theoretically possible to reduce the times even more by using higher temperatures and higher air velocities, the baker will soon encounter a zone of diminishing returns because the product's interior thermal conductivity becomes the limiting factor, not how fast the heat can be brought to its surface. The time and temperature reductions apply to many products. Even "Pullman" bread loaves (square sandwich bread baked in lidded pans) can be baked with about two-thirds the "time by driving temperature product." The accelerated heat transfer applies to metal as well, not just to exposed moist dough surfaces.

Baked foods' characteristics begin to change as baking times are adjusted by altering the temperature and heat transfer rate, either up or down. Baking is a complex series of reactions, many of which have

different Q_{10} (relative change in rate per each 10°C change in temperature) values. As a result, the rates for leavening release, fat melting, sugar dissolution, protein denaturation, and starch gelatinization will all differ at different temperatures, and the product will exhibit different properties when the baking conditions are changed, even if the internal temperature and moisture contents are held constant. Reformulation can compensate for these changes to only a limited extent.

Compact Footprint Designs

In many modern, large-scale wholesale bakeries, the oven is no longer a "stand alone" piece of equipment that must be "interfaced" at each end with the rest of the production line, but has become part of a totally unattended, integrated baking system. Product moves in a continuous, uninterrupted process, from mixing and depositing or filling at the beginning, with any proofing or relaxation required, through the oven, directly into coolers and freezers, without leaving the main conveyors, smoothly and quietly transferring trays where necessary. Manufacturing innovations include complete assembling of the entire production line and operating it to bake real product before it leaves the factory. Broken into smaller units for shipment, it can then be reassembled and put into operation relatively rapidly with a minimum of disruption to production flow in an existing bakery.

Totally automated and integrated systems like this are ideal for parbaking breads. Parbaking involves partially baking the loaves, so that they are firm and can be handled but they do not have full color development. The loaves are often shipped frozen to distribution points all across the country where they are finish baked in small rack ovens and sold to the consumer as fresh baked.

Horizontal folded path Like many other large-scale oven developments, the serpentine concept had its origins in small-scale ovens designed for retail bakers. Initially used as a small multipass cookie oven, the serpentine design borrowed concepts from the commercial traveling tray oven and produced a highly compact oven capable of baking large quantities in a small space. Trays are suspended on an extremely precise chain and guide system. They usually enter the oven near the bottom and progress from bottom to the top, typically making 7–11 closely spaced passes. In each pass, the trays are separated from those below or above by hot-oil-filled plate radiators served by a heat exchanger that can be located quite remotely from the production area, improving safety and sanitation. Most products baked in this system to date have been relatively thin ones, like cakes and cookies, but designs are available for full-size pan breads as well (Figure 9).

Figure 9 The horizontal path serpentine oven design conserves floor space and bakes very uniformly. It is often part of a totally integrated system that is preassembled and tested in the factory before it is installed in the customer's bakery. Thin thermal oil heat exchanger plates can be located between the horizontal runs of the conveyor and can provide much more uniform baking than side-fed recirculating air ovens, especially if the conveyors are more than 1 m wide. With a smaller external surface area to volume ratios and closer-spaced heat sources, the ovens are much more efficient than traditional designs.

The small cavity design retains humidity, and the large radiator plate surfaces close to the product result in unusually uniform product characteristics, energy efficiency, and low baking losses in addition to the obvious space savings. Instruments are now available to monitor oven humidity in real time and control it by operating dampers or even by direct steam injection.

Spiral circular path Spiral coolers and blast freezers are relatively common, providing very long paths and hence long residence times in a relatively compact floor space. The concept has also been applied to continuous ovens. Product enters the oven supported on large baking trays sometimes attached to the conveyor by magnets. The conveyor is a long, endless, spiral, usually entering near the floor level and winding its way upward through the large hot chamber. In some designs, the chain returns in a smaller spiral down inside the outer spiral, to exit the oven below the first spiral, where the product is removed and the conveyor is automatically and continuously reloaded with raw product. Heat is often supplied by direct combustion gas burners in the center of the oven, and fans may be used to blow the hot air at the products, maintaining a uniform temperature in the oven. Though very efficient in terms of baking surface per square foot of floor space, it is very difficult to incorporate temperature, humidity, or heat transfer "zones" into this design.

Vertical folded path Another approach to reducing floor space requirements is to operate the transport chains vertically, moving up and down through the oven as it progresses through the baking chamber.

Baking products are carried on swinging trays which remain horizontal as the transport chains move them through the oven chamber. Thermal oil heating plates may be arranged vertically between ascending and descending tracks or the ovens may be heated with forced circulation hot air. This design concept may have been inspired by the surge accumulator sections used in some automated packaging lines. This design can effectively change the path length through the oven, changing residence time "on the fly" for different products, without having to change belt speed. This is a large design advantage, though in most cases the radiant plates cannot be placed as close to or as effectively over the products as they can in the horizontal fixed-path design such as in the serpentine ovens. However, it is possible to change residence time in each zone essentially independently (Figure 10).

As the moveable double geared-pulley sets move up, the "forward" path shortens while the "empty return" path lengthens. This reduces the residence time in the oven but keeps the total chain length the same. Although a temporary regional speed change occurs while the geared pulleys are moving vertically, either the in-feed or discharge conveyor can be kept moving at a constant rate so they will not lose synchronization with either the filling or de-panning equipment. Baking times can thus be changed "on the fly" when products are changed. Since there is a great deal of thermal inertia in large oven systems, this can be a useful control for the baker because it will have a much more rapid effect than trying to change the temperature. Baking time and temperature can be stored in a computer as part of product manufacturing specifications. When the operator tells the computer that at a certain time a product change will occur, the oven can be programmed to adjust itself automatically.

Since the baking time can be changed without altering the chain speed, and hence production line speed, product is produced at a constant rate. In effect, the baking "tunnel" is lengthened for longer baking times or shortened for shorter times, all while the oven and the rest of the line continues in normal constant speed operation. This is not possible in most oven designs, especially in single-pass tunnel ovens. The same concept could also be applied to the horizontal folded path oven.

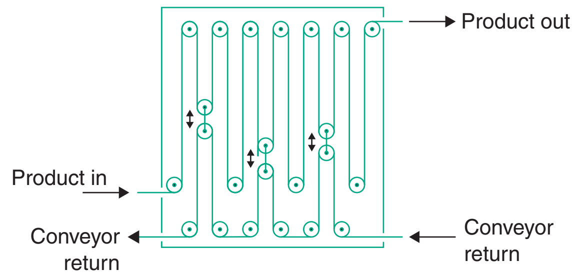

Figure 10 The vertical path serpentine oven design is also efficient in floor space (sometimes described as "small footprint" style) and can also be incorporated into an integrated baking system. Small trays remain suspended in a horizontal position while their conveyor moves through the oven zones. Thermal oil plates or infrared sources can be placed between the vertical conveyor paths. As the movable conveyor gears travel up, the product-containing section is shortened, matched by an increase in the conveyor return path shortens so the total conveyor length remains the same, but the baking time is reduced without changing conveyor speed.

Steam baking provides a high heat transfer rate Steam is often added to conventional ovens, sometimes to control the crust texture or color. It is also used as the principal energy source for Chinese-style steamed bread. In steamed breads, the object is to produce a relatively dense loaf with a chewy texture (varies with the style: "Northern," "Southern," or "Guang Dong") and a smooth, white, leathery surface, rather than a conventional browned crust.

Chinese steamed bread is made similar to conventional bread rolls in the early process stages, but after it has proofed and is ready to be baked it is placed on open or perforated racks in a steamer. Traditional designs use bamboo baskets, although metal trays are often used in larger or more modern bakeries. The bread is "baked" in saturated steam until it is heated through, the starch is gelatinized, the protein is denatured, and the loaves have a shiny but leathery surface.

Less Conventional Designs

Microwave baking Microwaves are familiar tools for reheating foods in the home or office and have been tried for large-scale baking. Microwaves have the advantage that the RF radiation passes easily through a dry crust and is absorbed largely by the moist inside portion. Provided the product is no more than ~10 cm in diameter, it heats relatively uniformly throughout. However, microwaves do not produce a brown crust and in the case of bread, a toughening often occurs. Domestic microwaves operate at 2450 MHz and industrial microwaves at 915 MHz in the United States. Some countries allocate different frequencies for these uses. It is very important to isolate these high-energy frequencies from other applications, so they do not interfere with communications, for example. The lower-frequency, longer-wavelength radiation penetrates most products much better.

Although there were numerous attempts to accelerate baking with microwaves as early as the 1960s, they were never commercially successful for

large-scale baking. In addition to the quality problems resulting from nonuniform field heating, they were very expensive to operate and difficult to control. Microwave generators (Magnetron tubes) are only ~50% efficient, converting about half the electrical input into heat. Their power level is also difficult to control. The most effective method has been "duty cycle," turning the tube on at full power for a short time, then turning it completely off. Although satisfactory for thawing foods or reheating them in domestic batch oven use, such a procedure does not work well in continuous conveyorized ovens. Also, trapping the radiation inside an operating oven, open at both ends for products on a nonmetallic belt to pass through, creates severe engineering challenges.

RF Ovens RF is used as an energy source in some ovens. RF is similar to microwaves but operates at a much lower frequency, hence generating longer wavelengths which are easier to contain. The energy penetrates deeper into the product and has fewer "hot spots" than with conventional microwaves. The frequencies allocated for this use in the United States are approximately 6, 13, 27, and 40 MHz. RF is used widely in industrial applications for curing plastics and providing controlled, localized, heating. In baking, however, it is principally limited to "postbaking" in the biscuit and cracker industry, where it has become very common since its successful commercialization in the UK in the 1960s. Thin products such as crackers are difficult to bake uniformly at high speed, because there are small variations in the dough composition, mixing and forming steps, and in the oven. As a result, the individual pieces may vary in moisture content and color as they leave the oven. Even if the product averages the target value (typically ~3%), when the moisture is too high in the center part of the cracker, it will cause checking or cracking as it equilibrates later.

By sending the still-hot crackers through a RF postbaking oven, the excess moisture is removed or equilibrated in a few seconds, resulting in more uniformity and less breakage. High-energy radio waves at these frequencies will preferentially couple with water molecules, drawing power to the wet portions but not to the dry ones. The small additional energy concentrated where the product needs it is sufficient to drive the extra moisture out, or to redistribute it, before the cracker has a chance to stress crack as it cools. This results in less dissatisfaction for the consumer and a greater profit margin for the baker (Figure 11).

Figure 11 RF postbaking section often follows a biscuit tunnel oven to reduce uneven moisture distribution which can cause broken product. (Courtesy of Radyne-Strayfield Corp., Milwaukee, WI 53207, USA.)

Baking with visible light "Visible + IR" light is another relatively recent concept for rapidly baking foods, especially at the retail fast food and food service level. A small microwave oven-size cavity contains tungsten–halogen tubes that emit a mixture of IR and visible wavelengths at extremely high intensity. The IR light does not penetrate very far beneath the surface, providing browning and flavor development as well as providing much of the total energy to the product. The intense visible light, shorter in wavelength, does penetrate somewhat into the interior. Though not as efficient in transmitting thermal energy, some is absorbed deeper into the products interior, thus accelerating the baking times considerably as compared with a conventional oven. It does not compete in speed with a microwave oven having a similar power rating, however.

Direct resistance ovens Ohmic heating is used in some specialized applications. To produce certain styles of bread crumbs, especially "Japanese style," for breading and battering foods such as fish sticks and deep fried vegetables, a simple bread dough is first mixed then the "loaves" placed between two electrodes and an electric current passed directly through the loaf. Careful control of dough moisture and salt content is necessary. The internal resistance of the moist dough generates considerable heat "internally" so in effect the bread bakes in its own steam. The moisture is driven off and the internal structure is set, but no crust browning occurs. After the loaf is removed and cooled, it is ground to the appropriate particle size and dried for use as a breading or batter thickener.

Hybrid Oven Designs

Hybrid ovens contain a combination of two or more energy sources. Technically, nearly all ovens might be

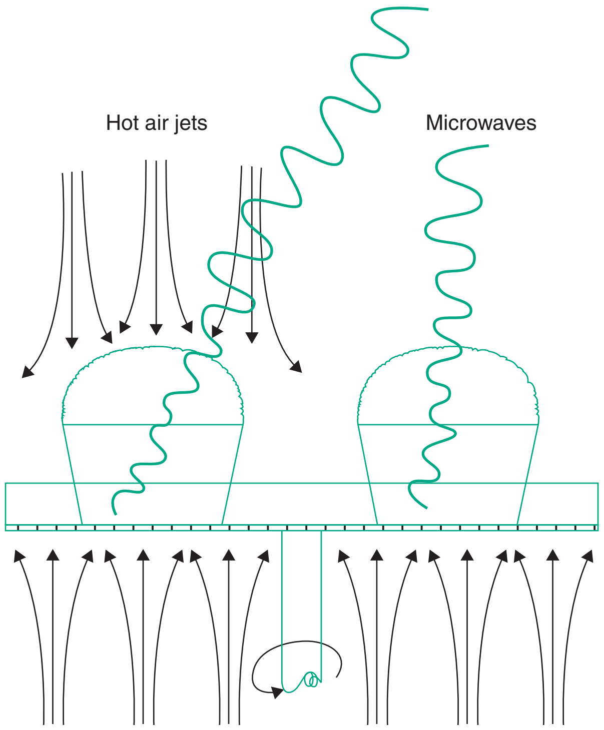

Figure 12 When baking in a hybrid oven, the food receives air impingement on all surfaces and also absorbs microwaves throughout. Keeping the product in motion results in a more uniform bake by distributing both forms of energy more evenly. (Reproduced with permission from Walker CE and Li A (1993) Impingement oven technology. Part III: Combining impingement with microwave (hybrid oven). *Technical Bulletin of the American Institute of Baking* XV(9): 1–6.)

considered “hybrid” because they usually use conduction, convection, and thermal radiation, all three to a certain extent. The term “hybrid oven” though is usually reserved for ovens that combine “nonconventional” energy sources, sometimes in a conventional oven, sometimes totally independently (Figure 12).

Microwave oven manufacturers have long offered (largely unsuccessfully) hybrid ovens to domestic customers in an attempt to combine the speed advantages of microwave with browning and flavor development. One variation includes adjustable radiant elements in the top of the cavity and another offered a bottom hearth plate, but neither were ever large sellers. One domestic range added microwaves inside the regular size oven, but the baking was rather uneven. The most popular were the so-called convection microwave ovens. A conventionally designed microwave oven contained a small fan to circulate air heated by a separate electric element. One major problem was that US domestic electrical circuits could not provide enough power to operate the microwave and the convection heaters at the same time, but had to cycle between them. A gas-fired hybrid microwave oven was developed in Europe, but sold only limited quantities. One major problem was in preventing the microwaves from extinguishing the gas flame.

Convenience stores and vending machines offer another potential market for microwave hybrid ovens, combined in this case with air impingement. They can be installed in commercial environments where they have access to sufficient electric power. The units are basically convection microwave ovens with oversized blowers and heaters that can operate at the same time as the microwave generator. Intended for food point-of-purchase consumption, the convenience store customer would buy a refrigerated or frozen dinner from the display cabinets, remove the wrapper, and cook it in less than 3 min.

An innovative extension to this idea was developed for the vending machine market. A large cabinet resembling a soft drink vending machine contained a freezer in the base where foods such as pizzas, spaghetti, and French-fries were kept inside ingenious design boxes. The top part contains a combination microwave and hot-air impingement oven. When the customer inserts coins, an elevator automatically selects the desired food from the frozen storage magazine below, lifts it to the top, and pushes the inner noncovered container out of the over wrap box into the heating chamber. The machine is preprogrammed for the amount of microwave and thermal energy needed to thaw, reheat, and brown the customer’s choice. The outer carton is then replaced and the hot snack delivered to the customer in 1 min. The concept has been used successfully for many years in remote military posts and in hospital food service operations, but has not yet become widely familiar to the general public.

Summary

Ovens have evolved slowly over thousands of years. Until recently though, the same principle – heating a food sitting on a hot shelf inside a closed chamber – described them all. Automation was not a major concept until a century ago, and innovative ways of generating and applying the energy to the product did not begin to make serious inroads in the home or commercial bakeries until the 1960s.

P

PASTA

M Sissons, Tamworth Agricultural Institute, Tamworth, NSW, Australia

Introduction

The word "pasta" is Italian for "dough" and is generally used to describe products fitting the "Italian" style of extruded foods such as spaghetti or lasagne. It is distinguished from the "oriental" style of sheeted and cut foods called noodles. There are over 600 pasta shapes, the most popular being spaghetti, elbow, macaroni, lasagne, and shells. Pasta can be sold fresh (as made in the home or restaurant) or refrigerated but most pasta is dried (with or without eggs), canned, or frozen. There are composite products, such as ravioli, cannelloni, lasagna, etc., in which pasta is combined with meat and vegetables in a tomato-based sauce, but the ingredients for making pasta are principally durum wheat semolina and water.

The wheat preferred is durum *Triticum turgidum* L. subsp. *turgidum* conv. *durum* (Desf.) MacKey (*see* **Wheat**: Genetics and Breeding). Durum wheat, in contrast to common wheat *T. aestivum* L. which is used to make bread and oriental style noodles, is the hardest wheat, and durum milling produces a coarse particle called semolina, ideal for making pasta and couscous. The key features of durum wheat include its hardness, intense yellow color, and nutty taste. After conversion to pasta, this wheat produces products with good cooking quality and stability to endure overcooking, with unmatchable eating quality. Several countries (Italy, France, and Greece) have decreed that pasta be produced exclusively from durum wheat and that the use of other cereals not mentioned is considered a fraud. In Italy, fresh pasta can be produced from common wheat flour or blends with semolina. Other countries such as Spain, United States, Canada, and Australia traditionally consume, by choice, pasta made from only durum wheat, but do not have a specific law on the matter.

This article provides a brief overview largely directed at dried pasta. It covers a brief history, the raw material requirements, and the manufacture of pasta from wheat milling to pasta drying. The assessment of pasta quality, its nutritional value, and the use of nonwheat sources to manufacture pasta is also discussed. The reader is encouraged to read the Further Reading section for much more detail on the subject.

Origin of Pasta

Indications are that pasta originated from China, although there is evidence of pasta use in Italy during the Etruscan civilization (several centuries BC). The earliest written record referring to pasta was in 1279 where pasta was included among the items in a will, referred to as a "bariscella plena da macaroni" (basket full of macaroni). By the sixteenth century, pasta makers in Italy were organized into trade associations and this quickly spread to France and other parts of Europe. Originally the production of pasta involved a batch process of manual kneading, cutting of the dough, and extrusion by hand press, followed by sun drying. In about 1800 the first mechanical devices appeared in Italy, and by the late 1890s equipment comprising mixers, kneaders, hydraulic presses, and drying cabinets became available. It was not until 1934 that the first continuous press system (where semolina and water are converted into wet pasta in a fully automated system) was developed replacing the batch method of pasta preparation and today all presses are of the continuous type.

World Production and Consumption of Pasta

The Mediterranean region is the world's largest producer of durum wheat (55–60% of world production) followed by North America (30%). Most of the durum wheat traded on the world market comes from North America. The annual durum wheat production globally over a 10 year period (1990–99) in selected countries was estimated to be 21.2–31.0 million tons (Mt). This was produced

on a harvested area of 14–16 Mha, but this represents only ~6–8% of the total global wheat production (Table 1). Annual pasta production from more than 30 countries amounts to ~10.3 Mt (Figure 1). Italy is traditionally the leading producer with the highest per capita consumption (Table 2). Demand in other regions such as North America, Oceania, and Asia has been increasing steadily.

Raw Material Quality Requirements for Pasta Products

Consumers of pasta are becoming more discerning in their quality requirements and less accepting of product variability. To achieve consistent quality, pasta makers must use raw materials that have the desired characteristics for processing into pasta. Currently, there are no standard measures of quality, and even for accepted parameters (as shown below) there is often disagreement over the methodology employed. Each parameter should not be viewed in isolation but used as part of a "picture of the quality" of the semolina (*see* **Cereals**: Grain-Quality Attributes). The important factors are given as follows.

For Wheat Grain

Appearance. Visual examination is very important to a buyer of wheat as it indicates how well the wheat will process. Most wheat-producing countries market wheat on the basis of its physical attributes.

Test weight. This is the quantity of grain that packs into a fixed volume. High values ($>80\,kg\ hl^{-1}$) indicate plump kernels undamaged by disease or environmental stress and this is correlated to the amount of semolina that can be produced from the wheat. Closely allied with test weight is the weight of 1000 kernels, which is also correlated with semolina yield, since large, plump kernels have more endosperm and hence, when milled, produce more semolina.

Physical defects. Grains with black coloration on the tips or in the crease of the grain will create

Table 2 Estimate of pasta consumption among selected countries (kg per head)

Country	*Consumption*
Italy	28.0
Venezuela	12.7
Tunisia	11.7

[a]Source: http://www.ilovepasta.org/sitemap.html.

noticeable black specks in the semolina. These specks will appear in the pasta and are especially noticeable in sheeted products. The most common surface discolorations are black point, smudge (fungal infection into the crease), and mildew. Fusarium, another fungal infection, reduces semolina yield due to kernel shrivelling and makes pasta redder and duller. Fusarium is also a safety concern because of associated mycotoxins such as deoxynivalenol (vomitoxin). Other fungi include ergot (*Claviceps purpurea*), *Alternaria alternata,* and *Dreschlera tritici-repentis* which produce dark specks in semolina.

Vitreousness. Durum wheat kernels should have a translucent, vitreous appearance to ensure good semolina yield. Nonvitreous or starchy kernels tend to produce more flour than semolina upon milling because they are softer. The percentage of vitreous kernels in a sample of wheat is an important grading factor used in trading in some countries. Low vitreous percentages are often associated with a low protein content.

Moisture content. The moisture content of the wheat will vary from 8% (arid areas) to 14% (temperate areas). The miller needs to know the grain moisture content in order to determine the conditioning profile before milling the wheat to produce semolina with a moisture content of 14–15%. High moisture content leads to greater microbiological growth.

Weather damage. Frost exposure of wheat kernels during grain maturation prevents them from completely filling out, thus reducing semolina yield. Grains that begin to germinate in the head before harvest due to damp, low-temperature conditions, have high levels of the enzyme called α-amylase. This enzyme degrades endosperm starch to produce sugars and can cause extrusion problems resulting in sticky pasta. The extent of sprouting can be measured by assaying for α-amylase or falling number. The latter estimates the thickness of a hot wheat-water slurry by measuring the time (in seconds) for a plunger to free-fall through the paste, where a short time is indicative of weather damage.

Protein quantity. The grain protein percentage forms a part of the wheat payments to farmers in some countries (e.g., Australia and Canada). High-protein semolina from durum wheats of good physical condition will generally yield semolina of uniform particle size with a minimum number of starchy semolina particles, and will hydrate evenly during mixing to produce pasta that is strong and elastic. When cooked, the pasta swells, leaving minimal residue in the cooking water, and remains firm to the point of serving. Semolina with low protein will produce pasta products deficient in some or all of these characteristics. A minimum protein content for pasta manufacture is ~12–15% (dry matter basis). Either the Kjeldahl (acid hydrolysis) or Dumas (combustion) methods are used to determine the nitrogen content in the grain (where % protein $= N \times 5.7$).

For Semolina

Ash. This is a measure of the mineral content (largely derived from the bran layers) remaining when all the organic content has been removed by combustion at very high temperatures. High extraction rates produce semolina with higher ash (0.9–1.1% dry weight basis) due to contamination by the bran and this reduces semolina's brightness and yellowness.

Protein quality. The protein type present in the grain affects processing properties. Gluten strength is a term used to describe the ability of the proteins to form a satisfactory network that promotes good cooking quality. The continuity and strength of the protein matrix formed during dough mixing and

extrusion is important in determining the textural characteristics of the pasta. Compared to weak gluten of the same protein level, strong gluten wheats exhibit less sticky dough with better extrusion properties and superior cooked textural characteristics. Experienced operators can judge the quality of this gluten by its feel in the hands; others need to use various physical tests. These tests include the sodium dodecyl sulfate sedimentation test, gluten index, farinograph, mixograph, and alveograph (*see* **Wheat**: Dough Rheology). Strength is particularly important for instant pastas since these have thinner walls and need more strength during processing. In contrast, popular fresh pastas require a more extensible dough and weaker gluten to improve sheeting properties. Thus, durum wheat or semolina specifications for gluten strength will vary depending on the type of final product being processed.

Color. A bright, yellow color in semolina ensures a good color in the pasta which consumers prefer. The main pigments in durum wheat responsible for the yellow color are xanthophylls and lutein. The yellow pigments can be partly degraded by the enzyme lipoxygenase during pasta processing. However, the high temperatures during drying denature the enzyme to make it ineffective. Color is typically measured using CIE (Commission Internationale de l'Eclairage) tri-stimulus values L^* (brightness), a^* (redness), and b^* (yellowness) with a chromameter or spectrophotometer. In addition, a brownish pigment caused by a copper protein complex causes a browning effect on the semolina which leads to a duller appearance in the pasta.

Speck count. Specks in semolina are caused by any material with a color that contrasts with the durum endosperm particles (brown or black). The black specks are easily detected in semolina. They also stand out clearly in the finished pasta. Brown specks arise from bran contamination and high levels indicate poor milling and/or high extraction rates. These are harder to see and their effect on pasta is to dull the appearance giving a gray effect to a normally bright product. It is impossible to completely eliminate these; therefore, an acceptable level is agreed upon between the miller and the pasta manufacturer. Measurement is normally done by visual inspection where the number of specks per unit area is counted.

Particle-size distribution. This is important since it affects the amount and uniformity of water absorption during mixing. Coarse particles hydrate slower than fine ones, and if there are too many fine particles in the mix, this will leave the coarse particles starved of water. These manifest as white inclusions in the pasta (white specks), which is unattractive to the consumer. For this reason the particle-size range should not be too broad since mixing time is limited in continuous flow mixers. The typical particle-size distribution has been decreasing since the early 1980s (in the past 630–125 μm) with common ranges now being 350–130 μm resulting in quicker and better water absorption and consequently, shorter mixing times.

Nondurum contamination. An acceptable tolerance is typically 3%. New techniques have been developed to accurately determine the levels of adulteration of durum wheat semolina or pasta with common wheat.

Typical figures for quality of durum wheat and semolina are best seen in the data for the three grades of Canadian durum wheat (Table 3). The data clearly illustrate what happens to the grade as some of the characteristics deteriorate.

Table 3 Quality data of the three grades of Canada Western amber durum wheat for 2000–01

Water

The water used should not have off-flavors or smells and needs to be monitored to ensure that it is safe and free from microbiological and chemical contaminants. It should not be too hard, have a low content of sodium, magnesium, and calcium ions as these would give an unpleasant flavor and color.

Other Raw Materials

Spinach has been used for many years and is usually added as a powder during mixing (~2% of the final product) to impart color. Tomato has also been used in much the same way. Egg imparts a change in color, texture, and increases protein content. It may be added in a liquid or dry state (four eggs – per kg of pasta). Vitamins are commonly used to fortify pasta in USA. These are added as a dry mixture ($1\,\mathrm{kg\,t^{-1}}$ semolina) and typically contain vitamin B_1, B_2, iron, and folic acid. Other additives include: acidifiers to give a sour taste (citric and tartaric acids); acidity correctors to modify pH of a food product (citric and lactic acids); emulsifiers to produce a homogeneous mixture of one or more immiscible phases in a food product (lecithins, fatty acids); preservatives to prolong the validity period of food products, protecting them from deterioration caused by microorganisms (sorbic acid); and flavor enhancers (monosodium glutamate).

The Manufacture of Pasta

An overview of the pasta making process is presented, but the reader is referred to more detailed accounts contained in the reference material.

Milling

The first step toward the manufacture of pasta is the milling of durum wheat to obtain semolina (*see* **Wheat**: Dry Milling). The wheat must be cleaned (by specific gravity) to remove impurities such as rocks, iron residues, straw, dust, insect fragments, and eggs. The wheat is then tempered to a moisture of ~15–16% for ~4 h before milling to toughen the bran. This ensures that the grain does not shatter excessively, as this would make it more difficult to separate bran from the endosperm in the purifier. Corrugated rolls are used to maximize semolina yield. Rolls with flutes aligned sharp-to-sharp further minimize flour production and maximize shearing during grinding. A long break system is used to allow the gradual release of coarse endosperm particles with a minimum yield of lower priced flour (Figure 2). Many purification passages are required to separate endosperm particles by their size and density. Passage through the rolling mills is alternated with sifting phases carried out by the plansifters and the purifiers. The plansifters, which are made up of superposed oscillating sieves of decreasing mesh size, have the task of separating the ground material according to particle size. The product that comes out of the plansifters is then conveyed, by pneumatic transport devices, to the next phases of the milling process shown in the diagram.

As the purifier sieve frame oscillates, an upward air current causes the material to stratify with the lighter bran-rich particles rising to the surface to float over the end of the sieve frame. The heavier endosperm particles fall through the sieve. After some initial purification, the stock is sent to sizing rolls to lightly grind the coarse particles releasing adhering bran and further reducing particle size. This is again purified and any material meeting the size settings is recovered as semolina and the rest goes onto the next sizing roll. A short reduction system is used to recover flour from the stock that is either too fine or too bran rich to be included in semolina. The reduction rolls have a smooth surface and are set closely together to release flour. Good purification is essential since bran or other dark particles are readily visible in the semolina. Commercial mills convert 65–75% of the wheat to semolina with 8–12% flour with the remainder being bran and embryo.

Mixing

This step involves combining semolina and water in a premixer. Water in a proportion of ~18–25% of the dry raw materials is added at 35–40°C, to achieve a freshly formed dough containing an average of ~30–32% moisture. After mixing (10–20 min), the mixture passes to the vacuum extruder (130 mm Hg) (Figure 3).

Extrusion

Dough is forced through a die in vacuum and at high pressure ($80–120\,\mathrm{kg\,cm^{-2}}$) and this gives the pasta its desired shape by developing the dough. The vacuum helps to minimize the oxidation of pigments, reduce enzymatic and oxidative decomposition reactions, and to decrease the likelihood of bubbles being incorporated into the dough, which can cause unsightly appearances in the final pasta. Dough temperature is kept below 50°C to avoid deterioration of the gluten matrix. Rectangular dies are used for long goods (spaghetti, etc.) and circular dies for short goods (shells, macaroni, etc.) (Figure 4). The feed holes of the die inserts are usually teflon coated to produce pasta with a smooth surface while bronze inserts are used to achieve a rougher pasta surface, which helps sauces to stick better to the cooked pasta. Teflon-coated dies achieve much higher throughput rates. After extrusion the pasta is immediately subject to a blast of hot air to minimize strands sticking together. The strands then enter the predryer.

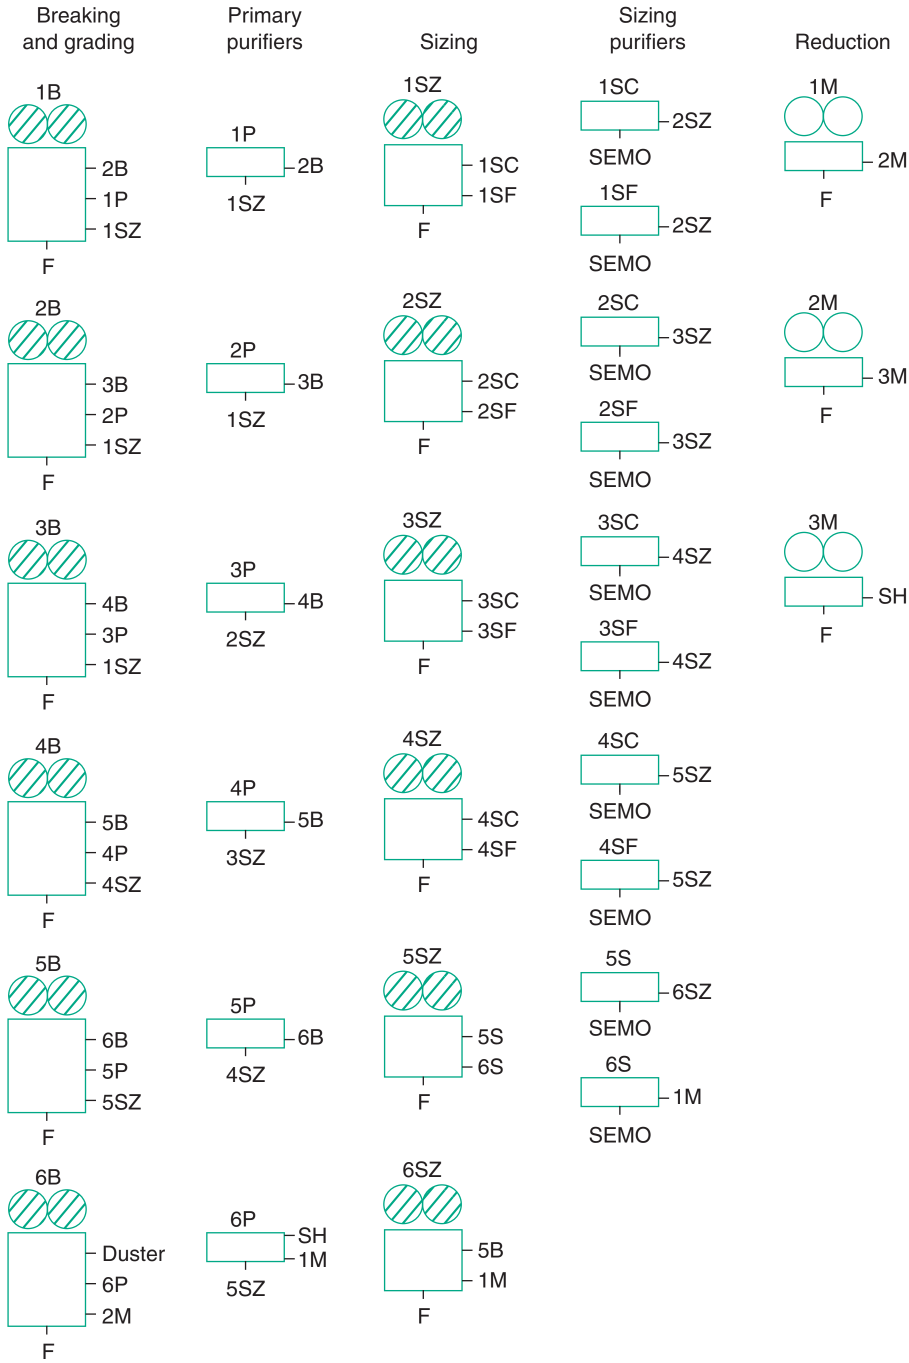

Figure 2 Simplified durum wheat semolina mill flow: B = break roll; P = purifier; SZ = sizing roll; F = flour; S = sizing purifier; SC = coarse sizing purifier; SF = fine sizing purifier; M = middling roll; SEMO = semolina; SH = shorts. (Reproduced with permission from Kruger JE, Matsuo RB, and Dick JW (eds.) (1996) *Pasta and Noodle Technology*, p. 98. St. Paul, MN: American Association of Cereal Chemists.)

Sheeting by extrusion and rolls There are a number of different sheeting die formats. The extruder with a 300 mm head rated at 350 kg h^{-1} gives a flat sheet of ~850 mm width. The sheet may be shredded to produce shortcut noodles, folded or presented as pasta Bologna. Such a machine can cut a wide range of different shapes that are stamped out while leaving an open lattice of reworkable material which is delivered to the feed stock of pasta dough.

Drying

The final step in the pasta-making process is drying. The purpose of drying is to produce a strong, stable

product with a final moisture content of ~12.5% with low water activity to ensure a long shelf life. Moisture is removed from the surface of the pasta by a stream of hot air creating a moisture gradient within the pasta. During the drying of pasta, it is essential that the outside surface of the pasta does not dry too quickly, otherwise a large moisture difference between the inside and outside of the pasta will occur. This causes "checking" or fracture lines to develop that will lead to breakage during packaging and storage. In severe cases, the strands will fall apart during cooking, destroying its appearance and therefore consumer appeal. The drier heat creates a permanent protein network around the starch granules, enhancing the strength and integrity of the pasta. This will prevent the starch granules from leaching into the cooking water and this will improve the firmness and bite of the cooked pasta. Excessive temperature during drying is undesirable, as it will result in brown discoloration of the pasta due to extreme nonenzymatic browning (Maillard reactions).

The pasta moves through a drying chamber and moisture falls from 30% to 12.5% and is then stabilized to ensure that any remaining moisture is evenly distributed. The product temperature is cooled down to that of the surrounding environment. Long goods which are draped over metal sticks move through the drier and the stick stacker. The pasta is then cut with high-speed stripper saws (Figure 5) to remove the bends (the portion of the strand which curves over the stick), trimming the product to the desired length. There are three different types of drying temperature used: normal temperature drying at 50°C for ~18 h; high temperature drying at 60–75°C for ~8 h; and ultrahigh temperature drying at 85–105°C for ~4–5 h (Figure 6). Ultrahigh temperature drying has become common with benefits to quality such as increased pasta firmness and higher yellowness and higher capacity.

The final product is then packaged into cellophane or polyethylene bags or cardboard boxes. Packaging is designed to keep the product free from contamination,

protect it from damage during shipment and storage, and display the product favorably while differentiating products. The typical yield for the complete process from milling to pasta is as follows: 140 kg of durum wheat produces 95–105 kg of semolina; 100 kg of semolina produces 98.5 kg of pasta.

Assessment of Pasta Quality

In traditional pasta-consuming countries the consumer is concerned about the aroma, color, appearance, texture, flavor, and nutritional value of the pasta. The pasta after cooking should maintain its texture and not become a thick, sticky mass (*see* **Cereals**: Grain-Quality Attributes). Mechanical texture is typically described by a range of terms (firmness, elasticity, stickiness, chewiness, and bulkiness) and can be measured by a sensory panel or by objective tests. Sensory evaluation is regarded as the ultimate test of pasta cooking quality and is the reference for which other methods are compared. However, some difficulties occur related to the different background and experience of the testers. To avoid subjectivity, various testing instruments have been developed to evaluate texture and all involve a means of deforming a sample and recording the force, time, and compression rate. Another test involves measuring by chemical methods, the total amount of organic matter released from the cooked

pasta after immersion in water for a fixed time. This test is highly correlated with sensory evaluation.

Pasta Products from Nonconventional Raw Materials

Although durum wheat semolina is considered the best raw material for pasta making, in some countries other ingredients are used to make pasta. Flours from other cereals such as oat, barley, millet, rye, maize, rice, sorghum, hulled wheat (spelt, emmer, and einkorn), triticale, khorasan, buckwheat, amaranth, or quinoa may be used to make pasta. Alternatively, raw materials from noncereals such as legume flour/starches (of chickpea, bean, pea, soybean, cowpea, and lentil), protein concentrates, and various animal proteins are used. Pasta has been produced from some of these raw materials for centuries in some Eastern countries. In the absence of durum wheat it is necessary to change the processing conditions, because unconventional raw materials have proteins of inferior quality and are not able to form a gluten network. Methods that modify starch structure help to produce a starch–protein matrix (e.g., gelatinization/retrogradation, pregelatinization of starch, and extrusion cooking) (*see* **Starch**: Chemistry and Modification). Other techniques include high-temperature drying to promote a protein network, the addition of selected additives, and fortifying raw materials with proteins. Yellow color can be enhanced by adding riboflavin, sunset yellow, β-carotene, and vitamin E.

Nutritional Value of Pasta

Pasta is considered a healthy food being relatively low in fat, high in carbohydrate, and having good protein content. Nutritional improvement of pasta mainly involves increasing protein and dietary fiber content and the fortification with vitamins and minerals (Table 4). High-protein flours (soybean, pea, lupin, and chickpea) can be added to increase the protein content of pasta to greater than 15% and improve the content of limiting amino acids, particularly lysine. To increase the content of minerals, vitamins, and dietary fiber, incorporation of buckwheat, whole wheat, artichoke, and amaranth pastas all claim health benefits.

Several studies have suggested that pasta reduces the increase in blood glucose in humans following a meal compared to an equivalent load of other carbohydrates, such as white bread. This is considered beneficial in reducing the risk of developing type II diabetes. Flavored pastas allow diet conscious consumers to have flavor (basil, garlic, parsley, and red pepper) without the addition of the high caloric sauces.

Pasta as a food represents an inexpensive means of improving diet quality in developed countries and helps to reduce hunger problems in developing countries. The unique combination of properties of cheapness, ease of preparation, versatility, nutritive value, and long shelf life will ensure that pasta will continue to play a role of importance as world demand for cereals increases.

Introduction

Pea (*P. sativum* L.) is one of the most ancient crop plants domesticated at around the same time as the major cereals. It is a cool-season plant requiring moderate temperatures in the range of 12–18°C with a relatively humid climate for optimum growth. Hot, dry weather is detrimental to seed set. However, it is also one of the most adaptable cool-season legumes and can give economic yields in areas that may not conform to the optimum requirement. A symbiotic relationship with *Rhizobium* enables pea to fix atmospheric nitrogen and make it available for the following crop. Thus, peas are of considerable significance in cropping rotations and overall economic value in the cropping system. The field pea plant has many uses. Green peas are one of the most popular vegetable items throughout the world. Some variants with edible pods are also used as whole pod vegetable, e.g., sugar podded peas, snow peas, etc. In some parts of Africa and Burma, leaves are used as pod herbs. It is also a forage plant that makes excellent hay and silage and can be utilized as a green manure crop. Dry peas are used as a whole in confectionery and snacks, milled to produce split peas for making soups, "dhal" (a curried soup-like preparation widely used in the Indian subcontinent), flour, and canned products such as mushy peas. Dry peas are used in the feed industry, particularly in the diet of pigs and

poultry due to their amino acid balance. This overview is focused on the production of the grain crop of *P. sativum*, referred to as dry pea or field pea.

There are over 6 million hectares (Mha) of field pea grown in the world today (**Figure 1**). As of early 2000s, Canada has the largest area under pea cultivation, followed by China, India, the Russian Federation, and France in that order (**Table 1**). Canada has dramatically increased its pea cultivation area from ~0.2 Mha to over 1.3 Mha since the 1990s. Canada also leads in the total production with more than 2 million metric tons (Mt) of crop produced in 2001, followed by France with a production of over 1.6 Mt. Eighty-eight percent of the total world production comes from the 10 highest field pea producing nations. The yield per hectare varies widely between growing regions. Amongst the largest producers, France has the highest yields per hectare of over 4 t against the world average of 1.68 t and the leading producer Canada's average yield is ~2 t. Average yields as low as 0.186 t have been reported from Croatia. In most countries where it is produced, pea seed is retained for domestic consumption. Canada, parts of Europe, the United States, and Australia are the major exporters.

The Plant

Field pea belongs to the family Fabaceae and although a number of *Pisum* species were designated for various cultivated pea types, they have all been assigned to *P. sativum* L. Some taxonomists, however, still insist on subdividing field pea, garden pea, and vegetable

pea into separate subspecies, although differences are often based on a few genes rather than broad genomic differences. All subspecies cross and recombine freely. Despite archaeological evidence indicating its cultivation as early as 6000 BC in Near Eastern and Greek settlements, there is no clear consensus on its exact place of origin. The Near East, Central Asia including Afghanistan, the Mediterranean, and Ethiopia abound with primitive forms and are sources of immense genetic diversity. A distinct species *Pisum fulvum* Sibth and Sm, partially cross-fertile with *P. sativum*, has been identified as a source of useful variation for disease and insect pest resistance and drought tolerance.

The plant, a spreading or tendril-climbing herb, is typically 30–150 cm tall (Figure 2). Papilionaceous flowers may be white or purple, or various shades of purple including pink. It is predominantly self-pollinated with cross-pollination rarely exceeding 1%. The stem is typically weak, leading to lodging as the plant gains weight. The compound leaves generally have one or more leaflets modified into tendrils, although variants are known which have no tendrils. Of significance are the forms where an entire leaf modifies to form tendrils (Figure 3) as this may help the crop to stand better by intertwining with plants. Greater attention to this character will be given while discussing genetic improvement. White flowered plants give rise to white, light greenish, or translucent testa, whereas colored flowers produce variously colored testa. Cotyledon color ranges from various shades of yellow to green, although genotypes with red cotyledon color are also known. The testa color largely determines the seed appearance, which is of commercial significance. Traders recognize five field pea seed types (Figure 4). The round white (also known as yellow), as the name suggests, is round with white to cream testa and yellow cotyledons. The dun type is variously dimpled with greenish brown (dun) testa and yellow cotyledons. The maple type is round with brown testa that is mottled with light colored spots giving it a marbling effect and yellow cotyledons. The blue type (also known as green) has a translucent testa with green cotyledons giving the seed a bluish hue. The marrowfat is typically a large seed (>280 mg) slightly dimpled and flattened with blue/green testa and green cotyledons.

Figure 2 *P. sativum* white flowered, normal leaf type showing pod and seed development.

The diploid chromosome number is 14. Chromosomal interchanges can be common. Considerable attention has been given to the genetics of pea following the pioneering experiments of Mendel in the nineteenth century. Several thousand mutants have been identified and those conforming to Mendelian genetics were placed on a linkage map as early as the middle of the last century. Updated maps, now including biochemical and molecular markers, have regularly appeared in *Pisum Genetics* (see below).

Nutritional Value, Processing, and Utilization

Field pea seed is a rich source of protein, carbohydrate, and some minerals, although the nutritional content of the seed varies with the environment and genetic factors. By far the highest proportion of the nutrient value of field pea is contained in the cotyledons, with the embryo and seedcoat contributing less than 10% to the nutritional value. The protein content is typically ~22% but ranges widely, depending upon the genotype and growing conditions (Tables 2a and 2b). Although sulfur-containing amino acid is low, it compares favorably with other grain legumes. About 60% of the carbohydrate content of the seed is made up of sucrose and oligosaccharides, starch, and crude fiber. The fat content is low and the seeds are a good source of vitamins such as thiamine, riboflavin, and niacin, although considerable loss of vitamins may occur in processing.

Antinutritional factors are present in quantities lower than in other grain legumes, and field pea has been found to have the lowest trypsin inhibitor activity among grain legumes commonly used as food in India. The flatulence activity resulting from oligosaccharides of the raffinose family is also relatively low, as are phytic acid and saponins. Lipoxygenase

activity that causes deteriorative changes during processing and storage of field peas has been found to be high, but these enzymes can be inactivated via heat treatment.

Dry pea seed is processed via soaking, germination, milling, cooking, roasting, or fermentation. In western diets the seed is mainly used in soups or in mushy pea preparations. In South Asian diets it has varied uses: as dhal (spicy soup-like preparation in the Indian subcontinent), whole pea boiled as a snack food, as sweet and savory snacks made from pea flour, or as a supplement to wheat flour to make nutritious breads. In addition, peas can be processed into protein, starch, and fiber fractions. These products can then be used in baked goods, baking mixes, soup mixes, processed meats, health foods, pastas, and purees. There are also several industrial starch uses.

Field peas also serve as excellent stock feed. In an amino acid balanced diet, there is no limit on the inclusion rate of field peas in ration for sows, weaners, and porkers. For poultry, it can be included up to 25% in rations. It may also be fed in high doses to ruminants as a palatable energy and protein-rich feed.

Genetic Improvement

The field pea yield is predominantly determined by the additive gene action, but nonadditive factors may also play a significant role. The heritability of yield may vary, depending on the environmental conditions leading to variable yield stability. The logical yield components are pods per plant, number of seeds, and seed weight. Among these pods per plant appears to be the best correlated with yield. However, selection for yield based on any one of these components is often ineffective. Further, the yield selection in early generations is not very effective as these generations are used for culling the population against easily recognized undesirable traits based on flower color, seed type, disease susceptibility, and plant type. Various breeding methods are in use and their application depends on the type and amount of genetic variation in crosses, objectives of breeding, and available resources. In Europe, the pedigree method is commonly used. Single seed descent is becoming popular to hasten the breeding and also to increase the frequency of desirable genes where recurrent selection is preferred. Bulk pedigree method has been successfully applied in Western Australian short-season environment where biomass appears to be an important asset in combating the terminal drought. Here, bulking early generation allows for natural selection to favor vigorous and tall plants.

There is considerable interest in restructuring the field pea plant since the discovery of a recessive mutant designated as afila (*af*) where leaflets are modified into tendrils. Plants with the afila characteristics are popularly known as semi-leafless, although strictly speaking they should be termed leafless. An increased number of tendrils in the semi-leafless crop helps plants to stand upright through intertwining with adjacent plants. When combined with dwarf plant stature and stiff stem characteristics, semi-leaflessness has considerably improved the standing ability of the crop. Improved standing ability has important

Figure 5 Blackspot on *P. sativum* caused by *M. pinodes*, the most widespread pea disease in the temperate zone.

implications in allowing for increased machine harvestation and enhanced aeration through the canopy that may help to reduce disease epidemics. Semi-leafless field pea varieties have become very popular in Europe, North America, New Zealand, some parts of Australia, and in countries such as India. However, in limiting environments of parts of Southern and Western Australia, conventional leaf types still outperform semi-leafless types. In such environments high biomass appears to be an important factor in determining yield, and semi-leafless types tend to have a lower biomass even at a high plant density. Breeding more vigorous and tall semi-leafless varieties presents a dilemma, as a heavier plant will tend to lodge because the stiff stem characteristic currently available is not able to support such a weight. In addition, dwarfing is counter-productive to high biomass.

Breeding against yield limitations such as diseases, insect pests, and abiotic factors has played a significant role in improving field pea yields. The impact of these factors varies with agro-ecology and crop management practices. Amongst the diseases, root rot diseases caused by *Pythium* spp. and *Aphanomyces euteiches* f. sp. *pisi* Pfender and Hagedorn and wilt caused by *Fusarium solani* (Mart.) Sacc. F. sp. *pisi* (Jones) Snyd. and Hans. are significant. The significant aboveground diseases are: (1) wilt caused by the bacterium *Pseudomonas syringae* pv. *pisi* Sackett, powdery mildew (*Erysiphe pisi* Syd.), and downy mildew (*Perenespora pisi* Syd.), and (2) black spot disease complex caused by *Ascochyta pisi* Lib., *Phoma medicaginis* var. *pinodella* (Jones) Boerema and *Mycosphaerella pinodes* (Berk and Blox.) (Figure 5). A number of viruses attack field peas with the most devastating being: pea seed-borne mosaic virus (PSBMV) and pea enation mosaic virus (PEMV). Of these, PSBMV is widely distributed throughout the world, whereas distribution of PEMV is more restricted.

Resistance is available against some root rots and wilt, powdery mildew, downy mildew, and black spots caused by *A. pisi* and *P. medicaginis* var. *pinodella* as well as the two important viruses – PSBMV and PEMV. However, it is resistance against the black spot caused by *M. pinodes*, the single most important disease of field pea throughout the temperate growing zones, which has been difficult to control through breeding. Only low to moderate resistance has been identified in several screening attempts of large germplasm collections in North America, Europe, and Australasia. More recently, over 3000 accessions from the Vavilov Institute, St. Petersburg collection were screened off-shore in Ethiopia by a Western Australian based project. The more pronounced expression of partial resistance has been identified in primitive accessions originating from Afghanistan, Ethiopia, and China. However, such accessions generally carry a number of wild characteristics including extraordinarily delayed flowering. Delayed flowering is recognized to help the field pea plant to resist *M. pinodes* and hence it is not always clear whether the resistance shown has a true genetic basis or is an artifact of late flowering habit. More recently, it has been found that there is some variation in reaction to *M. pinodes* infection within the improved germplasm and that small degree of resistance scattered in a wide variety of sources can be recombined. Both wild and improved sources have been used

in recurrent selection programs across Australia and New Zealand, and some new improved lines show resistance levels that are equal to or better than the wild germplasm. Developing resistant varieties to this pathogen will be a single most significant factor in increasing field pea yield in the major temperate growing areas.

The major field pea crop pests worldwide are pea and bean weevil (*Sitona lineatus* L.), pea moth (*Cydia nigricana* F.), pea aphid (*Acyrthosiphon pisum* Harris), pod borers (*Helicoverpa armigera* Hub. and *H. punctigera* (Wallengren)), and pea seed weevil (*Bruchus pisorum* L.). The red-legged earthmite (*Halotydeus destructor* Tucker) is more destructive in the southern hemisphere, e.g., Australia, where pasture legumes are widely grown. There has been some work on studying variation in resistance levels, but the most promising work so far has been on pea weevil (*B. pisorum*) in Australia. Resistance has been identified in a wild species *P. fulvum* that is partially cross-fertile with the *P. sativum*. Resistance has been backcrossed to field pea lines that should soon be ready for use as parent in crossing. Genetic transformation has also been successful in developing resistant lines and this will be described later in detail.

Waterlogging, freezing temperatures particularly during flowering and podding, and moisture stress are the most serious abiotic constraints to field pea productivity. No true resistance to waterlogging or frost has been reported so far. There are reports regarding cold tolerance, but whether it relates to avoiding damage during frost is not known. There are two aspects of freezing tolerance. In higher latitudes, such as Europe, freezing tolerance is important during the vegetative phase in the winter-sown crop, whereas in subtropical and Mediterranean climates frost tolerance during the reproductive stage is more important. A deeper root system has been reported to increase tolerance to moisture stress. However, osmoregulation/osmotic adjustment is a more measurable character and it has shown good correlation with yield under water stress in studies done in Spain and Western Australia. Recent studies in Western Australia have shown that the most adapted field pea variety showed one of the highest levels of osmotic adjustment.

Biotechnology and *In Vitro* Culture Techniques for Field Pea Improvement

Molecular Markers and Linkage Mapping

Molecular markers offer the potential to advance plant breeding by analysis of genetic variation, unequivocal identification of genotypes and true hybrids, purity testing of breeding lines, genome mapping, and marker-assisted selection. In field pea, classical physiological, biochemical, and hybridization-based markers such as restriction fragment length polymorphism (RFLP) have been joined by polymerase chain reaction (PCR) generated markers such as amplified fragment length polymorphism (AFLP), random amplified polymorphic DNA (RAPD), and short sequence repeats (SSRs). The polymorphic markers identified using these techniques are used to construct a linkage map of the field pea genome, indicating the position and relative genetic distances between markers along chromosomes.

When markers that are closely linked to desirable genes have been identified and validated in specific environments, plant breeders can use them to select plants on the basis of genotype rather than phenotype. The application of marker-assisted selection can reduce unreliable phenotypic screening and cultivar development time as markers enable the selection of genotypes at the seedling stage. Molecular linkage maps and trait mapping are valuable tools for characterizing the genetics of disease resistance, localizing resistance loci on linkage maps, and identifying linked polymorphic DNA sequences that might be used for marker-assisted selection. This is particularly true for traits that are inherited in a quantitative manner, for which quantitative trait loci (QTL) may be identified.

In field pea, a linkage map of the pea genome localizing QTLs for field resistance to *Ascochyta blight* and for plant developmental stage has been developed using classical and molecular markers. In addition, an RAPD-based genetic linkage map has been constructed, comprising seven linkage groups. Genetic relationships among *Pisum* accessions have also been assessed using random amplified microsatellite site (RAMS) type markers produced using SSR primers at low annealing temperatures. The largest distance observed was 22% and among *P. fulvum* accessions was 40%. The maximum distance between *P. sativum* and *P. fulvum* accessions was 46%. Interspecific hybridization to transfer useful traits from *P. fulvum* and wild-type *P. sativum* accessions such as ssp. *P. elatius* to cultivated *P. sativum* would also benefit from techniques such as marker-assisted selection and following QTLs. Targeted application of existing molecular techniques and the advent of new techniques such as the analysis of gene function through functional genomics will yield rapid gains in the understanding of field pea genetics.

Somatic Embryogenesis

The success of *in vitro* culture techniques such as transformation is reliant on the capacity of field

pea tissue to regenerate whole plants, usually via somatic embryogenesis. Somatic embryogenesis is the initiation and development of embryos from cells that are not products of gametic fusion. Somatic embryos are identical to normal zygotic embryos and are equipped with both the shoot and root pole and only need to be germinated to obtain complete plants. Somatic embryogenesis is useful for the rapid production of large numbers of plants from a single explant. In the absence of a system of nucleo-cytoplasmic male sterility in field pea, the cloning of the best hybrids by somatic embryogenesis and the production of artificial seeds could provide a means of utilizing hybrid vigor. In field pea, regeneration via somatic embryogenesis has been achieved from leaf-derived callus, shoot apices, immature zygotic embryos, and from protoplasts of zygotic embryo axes. Shoot apices and immature zygotic embryos are now routinely used as initial explants. Success in regeneration and especially in somatic embryogenesis is highly dependent on the donor plant genotype. In field pea, significant quantitative variation has been observed in inheritance of the ability to form somatic embryos with $\sim$80% of the observed genotypic variation due to additive gene effects. The distribution of F_3 family means from a cross between a line which was responsive to somatic embryogenesis and an unresponsive line indicated the presence of a few major genes in the control of somatic embryogenesis in field pea.

Transformation

Plant genetic engineering provides an opportunity to introduce traits such as pest and disease resistance, improved protein quality, and herbicide tolerance from previously unavailable sources. Since the first production of transgenic field pea plants in 1992, *Agrobacterium*-mediated genetic transformation has become a relatively routine procedure in a number of laboratories worldwide. The embryonic axis of immature seeds or the lateral cotyledonary meristems from germinating seed are the most responsive target explants, and regeneration is generally via organogenesis. A transgenic field pea genotype with significant pea weevil resistance has been developed in Australia. This cultivar is transformed with α-amylase inhibitors, which confer 99.5% resistance to pea weevil in glasshouse and field trials.

In addition to *Agrobacterium*-mediated transformation, several other approaches have been developed to produce transgenic field pea plants: transgenic callus has been obtained by electroporation of protoplasts, as has transient expression following particle bombardment of meristems. Microinjection, particle gun, agroinfection, or the pollen tube pathway are at present less efficient or require expensive and sophisticated equipment. As in other species, transformation efficiency is dependent on the genotype, explant type, and other physical parameters. Community acceptance of cultivars developed via the transformation technique will determine the future of this technology.

In Vitro Mediated Interspecific and Intergeneric Hybridization

Interspecific hybridization is the crossing of two species from the same genus. This allows the exploitation of useful genes from wild, unimproved species for the benefit of the cultivated species. The *Pisum* species are diploid self-pollinators sharing a similar karyotype. *P. fulvum* is the only separate wild species, and a useful source of disease and insect resistance. Fertile hybrids of *P. sativum* $\times$ *P. fulvum* have been produced via conventional unidirectional crossing with *P. fulvum* as the pollen donor.

Intergeneric crossing is a further technique for improving genetic diversity within species. It is possible to regenerate plants from protoplasts in field pea via organogenesis and somatic embryogenesis. Somatic protoplast fusion, whereby genomes from different genera are combined without pollination through protoplast fusion, has been attempted for intergeneric hybridization between field pea and grass pea. A low frequency (5%) of protoplast fusion has been achieved; however, these hybrids have not been regenerated to whole plants.

Double Haploid Production

Doubled haploids (DHs) are plants derived from a single pollen grain and doubled artificially to form homozygous diploids. A DH individual has two identical homologs, so that the amount of recombination information is equivalent to a backcross. The advantage of using a DH population in molecular mapping is that all individuals are homozygous. Therefore, DHs may be transferred between different laboratories and environments for assessing the effect of the environment on gene expression. Field pea, along with many of the large seeded leguminous species, has traditionally been considered recalcitrant to this technique. Recently, success has been reported in producing embryos from isolated microspores of field pea. Research is ongoing to overcome barriers to further embryo development and plant regeneration. Successful production of doubled haploids on a routine basis would reduce cultivar development time, and provide excellent recombinant inbred lines for molecular mapping applications. The

development of doubled haploid plants also has a direct implication on breeding as it achieves homozygosity in segregating populations in a single generation as opposed to five to six generations using a conventional breeding cycle. This enables selection of stable lines to start much earlier.

Grain Quality and Marketing

Market requirements for grain quality relate predominantly to shape, size, and color (testa and cotyledon). For all seed types large size is desired, and in marrowfat there may be a limit for the minimum seed size from the buyer. With blue pea, resistance to bleaching is an important criterion. Round white types must have smooth round surface with white to creamy color and bright yellow cotyledons. The dun types should ideally have a mix of greenish to brownish testa, fewer and shallower dimples with bright yellow cotyledons. Maple type that is mainly used for pigeon and bird feed must have white markings on a brown testa and yellow cotyledon. Both round white and dun types are milled, as are blue types. However, currently there are no standards for milling recovery. Seed moisture content at sale is normally between 10% and 15%. All types of field peas are generally accepted by the feed industry, but a preference is made for the noncolored type as they tend to have less antinutritional factors. The Southeast Asian market for sprouting field pea prefers dun types with large seed size and fewer hard seeds. Irrespective of the type, the following qualities are important for visual assessment in the trade:

- levels of admixture,
- levels of insect damage and presence of live or dead insects,
- product color,
- product size,
- product cleanliness, and
- product uniformity.

About one-fifth of the field pea production is traded throughout the world, which compares with temperate cereals where ~5% is traded. The world field pea production has been declining in recent years, but trading across the board is showing a slow increasing trend. The prices have been generally steady since the early 1990s, but wide variations occur depending upon the season, time of the year, and proximity to the market. Canada and France are the world's leading exporters with Canada dominating the export in recent years. The Netherlands is the largest importer of field pea with Germany, Spain, Belgium, and Luxembourg emerging as rapidly growing importers. Demand for field pea from India is also increasing.

In general, the market for field pea is rather unsophisticated both in terms of product definition and in terminology used. For instance, in dun-type field peas that are normally milled, traders often use slight variation in testa color in an attempt to discount price that is irrelevant to the product utilization. There are various terminology used to describe the same product as in the case of white round type that is traded as yellow pea from North America. To address this issue some major exporters met at Winnipeg, Manitoba, Canada in 2000 for the International Pulse Quality Committee Meeting. They resolved to initiate a process to facilitate marketing of pulses through development of standardized nomenclature and methods of testing quality parameters in order to meet consumer needs. The Committee aimed at approaching International Pulse Trade and Industry Confederation (CICILS/IPTIC) and various major importing organizations to report their work and consult on future developments. It is expected that standardizing nomenclature and methods for quality evaluation will facilitate improvement of quality assurance in the international pulse trade including field peas. There has been limited progress so far, but updates on developments will be regularly posted on the CICILS website.

Introduction

Pea (*Pisum sativum* L.) is commonly grown in temperate areas of all continents. It has many uses: immature pods and seeds are used as green vegetables, either fresh or frozen; it is used as green forage for grazing animals, *in situ* or as hay or silage; and it is grown for its mature seed, which itself has many uses. Growing pea for its mature seed is the focus of this article.

Pea grown for grain is known variously as field pea, dry pea, combining pea, or protein pea (French *pois protéagineux*). It is grown in rotation with cereals and oilseeds in a wide range of environments, always as part of an integrated farming system. In North America and northern Europe, pea is generally sown in spring, harvested in mid-late summer, and followed by winter wheat. It is not commonly grown more than once every 4 years on the same land, and the rotation could also include winter wheat or barley, spring wheat or barley, oilseeds, or other grain legumes. In southern Europe and Australia, pea is sown in autumn or winter, harvested in early summer, and usually followed by wheat. In this case as well growing pea more than once every 4 years is not desirable, and the rest of the rotation comprises cereals and oilseeds. Pea is mostly grown under dryland conditions, but will respond to irrigation. However, limited resources for irrigation are often better used on higher valued crops, such as sugar beet and potatoes in the UK.

Farming System Benefits of Pea

The most important reason farmers grow pea is for the benefits conferred on other crops in rotations. The most obvious benefit comes from pea's ability to

Table 1 Productivity and profitability of a rotation based on spring pea on the management of herbicide resistant blackgrass (*Alopecurus myosuroides* Huds.)

Rotation	*Blackgrass population 1999 (plants m^{-2})*	*Winter wheat yield 1998–99 (t ha^{-1})*	*Direct margin[a] 1996–99 (Euros ha^{-1})*
Continuous winter wheat[b]	13.0	6.4	407.0
Spring barley-spring pea-winter wheat[b]	3.4	7.9	604.4

[a] Direct margin was defined as gross income minus protection costs, tillage costs, and crop seed costs, and is averaged over the whole life of the experiment.
[b] Rotations compared over three seasons (1996–97, 1997–98, 1998–99) on a site where blackgrass had developed resistance to aryloxyphenoxy-propionate herbicides after 13 winter crops in 16 years and seven applications of fenoxaprop-P-ethyl or clodinafoppropargyl in the last 6 years. Figures for the winter crop rotation are averaged over three cultural strategies differing mainly in intensity of herbicide use, and figures for the spring crop rotation are averaged over four strategies.
Source: Chauvel B, *et al.* (2001) *Crop Protection* 20, 127–137.

acquire its own nitrogen (N) from the atmosphere, some of which is left in the soil where it can be used by following crops. One study in Western Australia found that wheat grown after cultivation of pea yielded 41% more grain, and averaged 1.7% more grain protein, than wheat with no added N fertilizer after wheat cultivation. Similar results have been obtained in North America. A common rule of thumb in the UK is that pea gives an extra ton per hectare of winter wheat. Pea also contributes to the farming system by breaking life cycles of diseases that affect other crops, and by allowing more flexible weed management. This is true even when weeds develop resistance to selective herbicides, which is happening increasingly in Australia, Europe, and North America. In France, pea rotations enabled successful management of herbicide-resistant populations of black grass (*Alopecurus myosuroides* Huds.). In this case, growing spring pea rather than the more profitable winter cereals allowed nonselective control of weeds germinating in late autumn and early winter. This gave better subsequent wheat yields, and a more profitable rotation overall (Table 1). In the Mediterranean, agricultural environment of southern Australia where early sowing is crucial to maximizing yields of cereals, oilseeds, and other grain legumes such as lupin and faba bean, pea increases opportunities for nonselective weed control because it is usually sown later.

Despite these benefits, farmers in many parts of the world are wary of growing pea. Pea usually yields less grain than wheat or barley, so is not generally as profitable in its own right as these crops. This is an important reason why farmers do not grow more peas in many European countries, and in Australia. Pea grain yields are also more variable from year to year than cereal yields. In Germany, it has been suggested that growing mixtures of pea with faba bean results in less season-to-season yield variability than either crop on its own. But the biggest disincentive to growing peas is harvesting. Even the most erect pea cultivars are prone to lodging at maturity, and many lodge completely. This means that, even with expensive harvester attachments to assist picking up the crop, harvesting pea is slower, and the likelihood of causing serious damage to the harvester, by putting soil or stones through it, is greater than harvesting other crops.

Adaptation of Pea

Soils

Pea is best suited to sandy loam through to clay loam soils with neutral pH. It will, however, grow on a more diverse range of soils than other grain legumes. For example, in Australia it can be grown successfully on soils with pH ranging from 4.5 to 9.0 (measured in a 1 : 5 soil extract in 0.01 M $CaCl_2$), although lupin is better adapted at the acid end, and lentil at the alkaline end, of this spectrum. Pea is not so well suited to very sandy soils, on which premature water deficits can develop as a consequence of its shallow root system. In environments with long dry periods after harvest, fragile pea stubbles on sandy soils are also at great risk from wind erosion. Neither is pea very well suited to very heavy soils with poor internal drainage because the crop is very sensitive to waterlogging.

Rainfall

Pea is one of the best-adapted grain legume species to dry environments. Vigorous early growth, early flowering of most cultivars, and early maturity mean a greater proportion of growth occurs under cool, humid conditions, and therefore water-use efficiency is higher than in species like lupin and chickpea. This applies both to spring-sown crops in North America and winter-sown crops in Australia (Table 2), and means in very dry seasons pea will produce at least some grain while other grain legumes may produce none at all. However, it also limits the ability of pea to respond to better growing conditions, so pea yield is often more stable across seasons than the yield of other grain legumes (Figure 1).

Table 2 Water-use efficiency (kg ha^{-1} mm^{-1}) of a number of grain legume species in North America and Australia

	North America			*Australia*
	Saskatchewan[a]	*Northern Great Plains*[b]	*North Dakota*[c]	*South-west Western Australia*[d]

Growing a Pea Crop

Cultivar Choice

There is considerable diversity among pea cultivars. Initially, the type of pea to be grown must be chosen: whether white (yellow), blue (green), marrowfat, dun or maple; and then a cultivar among these types chosen. The type of pea will depend largely on market possibilities. Most peas produced in Europe and North America are white (yellow) or blue (green), and most in Australia are dun. Taking advantage of the higher prices for blue (green) or marrowfat peas requires more attention to grain quality than for other types. In particular, in dry environments achieving large enough seed to satisfy market requirements is difficult.

Great improvements have been made in the standing ability of pea cultivars over the past 30 years. This is due to improvements in stem strength, shorter internodes, and use of the semileafless or *afila* character. Semileafless pea has more interlocking tendrils than conventional leafed plants, and therefore forms a more rigid canopy framework than conventional pea. These canopies are better able to withstand the wind-imposed shearing forces that normally cause pea canopies to lodge. Nearly all European and North American pea cultivars are semileafless, but most cultivars grown in Australia have conventional

leaves. Semileafless cultivars are likely to become more prominent in Australia over the next decade.

Another important criterion for cultivar choice is disease tolerance. There are cultivars resistant to powdery mildew (*Peronospora viciae*), downy mildew (*Erysiphe pisi* f. sp. *pisi*), bacterial blight (*Pseudomonas syringae* pv. *pisi* and pv. *syringae*), *Fusarium* wilt (*Fusarium oxysporum*), and several virus diseases. Breeders around the world are also devoting considerable effort to improving tolerance to *Ascochyta* and *Mycosphaerella*.

Sowing Time

In the Mediterranean environments of southern Europe and southern Australia, sowing time is determined by rainfall pattern, although in Australia it is further complicated by the need to avoid *Mycosphaerella* blight. In northern Europe and the Great Plains of North America, avoiding the cold winter is also important.

In Mediterranean environments hot, dry summers are followed by cool, moist winters. Spring becomes progressively hotter and drier. Annual crops like pea are sown in late autumn or early winter, grow over winter and spring, and mature in late spring or early summer. Sowing crops as soon as the soil is moist enough to support plant growth enables it to achieve most of its growth under cool humid conditions conducive to high water-use efficiency, as well as maximizing the length of the growing season. It also allows grain-filling to occur under cooler, moister conditions because early-sown crops flower earlier than late-sown crops. In Australia, pea is usually sown later than other annual crops. Its early maturity relative to other crops means it doesn't lose yield as quickly when sowing is delayed, but the real purpose is to reduce *Mycosphaerella* infection. This is discussed further below.

Where soils freeze in winter, sowing must be delayed until the soil is warm enough for germination– at least 4–5°C. There are winter cultivars, whose seedlings survive a certain amount of freezing after autumn sowing. Some of these are grown in France, but spring pea is more common. Sowing as soon as the soil is warm enough maximizes yield potential for the same reasons that early sowing does in Mediterranean environments. However, sowing too early can expose young seedlings to frost damage. If the aboveground parts of the seedling are killed, new shoots regenerate from subsurface axillary buds. In Canada, an early sown, frosted but regenerated crop often has as good a yield potential as a late-sown unfrosted crop. Early sowing also increases the risk of frost during early pod growth. This can devastate yields. Frost damage during pod growth also occurs in Mediterranean environments, but in Australia spring frosts are sufficiently unpredictable to have only a minor bearing on sowing time decisions.

Sowing Management

Traditionally, pea was sown into cultivated seedbeds. This still happens, but in North America and Australia, it is increasingly being sown into undisturbed soil, often into standing cereal stubble. This reduces the risk of soil erosion from both wind and water, reduces the degradation of soil structure resulting from excessive cultivation, and avoids mixing weed seeds through the top 15 cm of soil, which can lead to more late-germinating weeds in the crop. Retention of standing stubble can improve crop water relations by trapping snow in the preceding winter, which adds to soil moisture storage in North America, and reducing evaporation from the soil surface by creating a thicker boundary layer. Standing stubble can also provide extra support to pea plants, which facilitates harvesting, but may delay spring sowing by retarding soil warming.

Pea should be sown 4–8 cm deep. Sowing at the shallow end of this range is an advantage for very early spring sowing into cold soil, but deeper sowing is preferable in environments where the soil surface dries rapidly. Crop damage from soil-applied herbicides is less with deep sowing.

Pea grain yield increases with increasing plant density when densities are low, but the rate of increase gradually declines until yield reaches a plateau, or even begins to decline (Figure 2). Simplistic analyses of this response choose the density at maximum yield

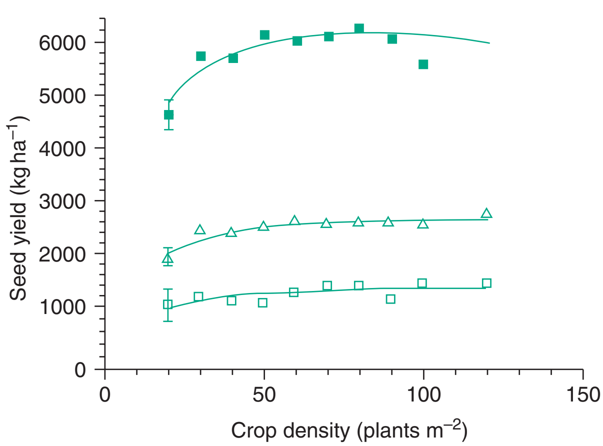

Figure 2 Grain yield response of field pea *cv.* Swing to plant population density at seven locations in Saskachewan, Canada in 2001. Open squares – Swift Current, lowest yielding site, closed squares – Outlook, highest yielding site, triangles – average of seven sites. (Reproduced with permission from Johnston AM, *et al.* (2002) *Canadian Journal of Plant Science* 82, 639–644.)

as the target farmers should aim for, but the greater cost of seed compared to the grain produced means that the true economic optimum occurs at a lower density. In addition, grain yield is not the only criterion used to make plant density recommendations. Generally, it is better to err on the high side rather than the low side because dense crops compete better with weeds than thin crops, and have more interplant connections via tendrils, thus forming a more rigid canopy, which will better resist lodging. Dense canopies facilitate harvesting of prostrate conventional leaved cultivars too because, even though they invariably lodge, their interplant connections aid crop feeding into the harvester. Recommended target densities from various parts of the world are given in Table 3.

The necessary seed rate to establish the target density depends on seed size, percentage germination, and seedbed losses. In the UK, the following formula is recommended for calculating seed rates, and similar formulas are used elsewhere:

$$\begin{aligned}&\text{Seed rate (kg ha}^{-1})\\&\quad = (\text{Thousand seed weight (g)}\\&\qquad \times \text{target population (plants m}^{-2}) \times 100)/\\&\qquad (\%\ \text{germination} \times (100 - \text{seedbed losses}))\end{aligned}$$

Seedbed losses in Europe are greater with very early sowing when the soil is cold: UK growers expect losses as high as 15–18% for February sowing, but only 7–8% for April sowing. In Australia, seedbed losses are generally less than 10% and are often ignored in seed rate calculations. Using the seed rate formula requires knowledge of the thousand seed weight and germination %, for which each seed lot must be tested. In Canada and UK, an electrolyte leakage, or electrical conductivity (EC), test is available for seed vigor. This is related to the number of microscopic cracks in the seedcoat, resulting from mechanical damage at harvest. These cracks allow substances that can stimulate pathogen growth to leak from the seed into the surrounding soil. Only the highest vigor seed (lowest EC value) should be used for early sowing into cold soil but less vigorous seed may be suitable for later sowing.

The soil surface should be left as even as possible after sowing, and free from stones, stumps, and other obstacles that could interfere with harvesting. This is especially important with conventional leaved cultivars that are prostrate at harvest, but also applies to modern, erect, cultivars that still sometimes lodge. Rolling pea crops after sowing helps by pushing rocks under the surface and crushing soil clods that might otherwise damage harvesting machinery. In some cases, heavy rubber-tired or steel rollers are towed behind sowing machinery, but pea can be rolled without significant damage until plants are ~15 cm high. Rolling before emergence is preferable because a rolled crop must be allowed to recover before any postemergent herbicides are applied. Rolling when the crop is emerging should be avoided because emerging seedlings are very fragile.

Table 3 Recommended target plant densities in selected pea-growing regions of the world

Country	*Target plant density (plants m^{-2})*	*Other specific information*
United Kingdom[a]	65	Vigorous marrowfats
	70	Large blues and whites
	95	Early maturing small blues
Canada (Alberta)[b]	75–90	
Australia (Victoria)[c]	40–60	Tall varieties
	70–80	Semidwarf varieties
Australia (Western Australia)[d]	45	Tall conventional leafy types
	55	Semileafless and semidwarf types

Crop Nutrition

Nitrogen (N) Pea requires the same plant nutrients as other crops but, as it is a legume, there is usually no need for N fertilizer if the crop is well nodulated. Pea forms root nodule symbioses with *Rhizobium leguminosarum*, which also forms symbioses with a number of other agriculturally important legumes, including faba bean, lentil, and vetch. It is different from the species that infect clover, medic, lupin, or chickpea roots. In Europe, *R. leguminosarum* is widely distributed in agricultural soils, so good nodulation can be achieved without seed inoculation. It is not so widespread in North America or Australia, where seed should be inoculated if sowing into soil that has not grown pea before. Trials in Australia show that inoculation can more than double grain yield under such circumstances. *R. leguminosarum* is not particularly acid tolerant, so does not survive as well in acid as in alkaline soils. In Australia, it is recommended that all pea crops be inoculated if sown on soils with surface pH ≤6, whether or not pea has

been grown previously. Inoculum has traditionally been applied to seed as a slurry of peat-based culture in water or a methyl-cellulose solution (this aids adhesion to the seed) but more recently granular inocula on various carriers have been developed. These are placed in the seedbed at sowing rather than applied to the seed beforehand. The granular inocula have a longer shelf life than peat-based cultures and do not require refrigeration. Seed-applied inocula also have the disadvantage of having to be applied to the seed within a few days of sowing since the bacteria do not survive long on the seed surface. Fungicide seed dressings can be toxic to rhizobium on the seed, and large nodulation and yield reductions are possible. Recent Canadian research has shown that granular inocula are more effective on pea than inocula applied to the seed both in the presence and absence of the fungicides, metalaxyl and thiram.

While there is generally no need to use N fertilizer on pea, small amounts can be beneficial under certain circumstances. Pea seedlings depend on soil N before effective nodules form and in both Canada and Australia 5–20 kg ha^{-1} of starter N is recommended on soils with very low mineral N. Effective nodules are slower to form in acid soils, and starter N can be helpful even when mineral N levels are relatively high (Figure 3). Higher rates of N can suppress N fixation and, in Canada, delay crop maturity and promote disease and lodging.

Phosphorus (P) Many soils on which pea is grown are P deficient, especially in their native state. Furthermore, much phosphate applied to soils is immobilized in insoluble forms before plants can use it. Many European soils have been farmed for a long time so their capacity to immobilize P is close to saturated, and here P fertilization is basically replacing what is removed in grain. In North America and Australia, more P is usually necessary. The appropriate rate depends on soil P content, which is determined by soil analysis, and recommendations are based on locally developed calibrations. 20 kg ha^{-1} P is a typical application rate, but higher rates are necessary on some soils.

Potassium (K) and sulfur (S) Pea grain contains considerable amounts of K and S (Table 4), and pea requires more of these nutrients than cereals. The need for K is also diagnosed by soil analysis, and in Europe K deficiency can be more significant than P deficiency. In Australia, many soils naturally contain sufficient K that no more needs to be added. This is especially true of the heavier-textured soils where pea is usually grown, but will change in the future as native reserves of K are depleted and higher yielding cultivars with higher K requirements are adopted. K fertilizers are very soluble in water and high rates can have adverse osmotic effects on germination if drilled with the seed. In Europe and North America, K fertilizer is banded a few centimeters below or beside the seed to avoid this. In Australia, P fertilizer is sometimes banded below the seed, but K fertilizer is often broadcast either before or after sowing. Its high solubility means it is rapidly leached into the crop's root zone by winter rains.

Much of the P fertilizer used in the past contained considerable amounts of sulfur, so S deficiency is uncommon. It is sometimes seen in North America and Europe but rarely in Australia.

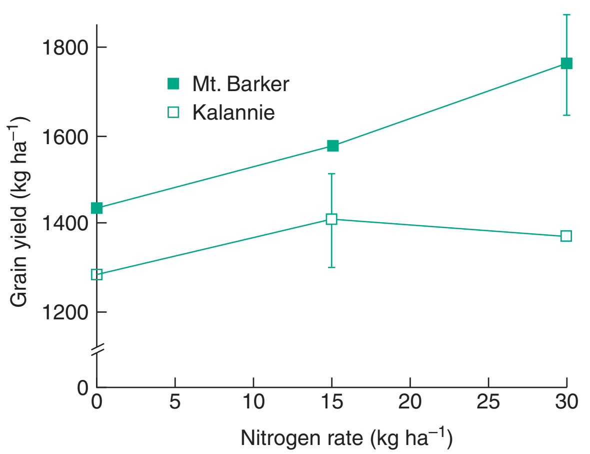

Figure 3 Effect of starter nitrogen on field pea *cv.* Dundale at two sites in Western Australia in 1997. Nitrogen was applied by top-dressing urea at sowing. Vertical bars represent the least significant difference at the 5% probability level.

Table 4 Average amount of plant nutrients removed by 1 t of pea grain[a]

Nutrient	*Quantity removed in 1 t grain*
Nitrogen (kg)	37
Potassium (kg)	9.1
Phosphorus (kg)	4
Sulfur (kg)	2
Magnesium (kg)	1.2
Calcium (kg)	0.9
Iron (g)	59
Zinc (g)	26
Manganese (g)	20
Copper (g)	7

Kingston, ACT, Australia: Grains Research and Development Corporation; and Hickling D (ed.) (1997) *Canadian Peas Feed Industry Guide*, pp. 21. Winnipeg, MB: Canadian Special Crops Association; and Regina, SK: Western Canada Pulse Growers Association.

Micronutrients The most commonly deficient micronutrients are manganese (Mn), zinc (Zn), and molybdenum (Mo). Mn deficiency causes a disorder known as Marsh Spot, and can occur in all pea-growing regions. It is more common in Europe than elsewhere. Zn deficiency is most common in Australia. Both Mn and Zn are less available on alkaline soils, so deficiencies can be induced by excessive liming. Mo is less available on acid soils, so liming can correct a deficiency. In general, if micronutrient levels are adequate for cereals, they should also be adequate for pea. Soil tests have been developed for micronutrients, but regular tissue testing of crops is the best way to diagnose developing deficiencies.

Weed Management

Pea is not particularly competitive against weeds, and weed control in a pea crop can be troublesome. Herbicides are almost essential for producing a good crop, and the modern trend to reduce tillage has increased reliance on herbicides. Fortunately, more herbicides can be used in pea than in any other grain legume: there are currently 218 herbicide products registered for use on combining pea in the UK (many of them have the same active ingredient though: 122 of them contain glyphosate). Weed spectrum and farming system vary enormously between the world's pea-growing regions, so only general principles will be outlined here. Regional literature should be consulted for details on specific herbicides and weeds.

The potential weed burden should be reduced as much as possible before the crop is sown. This fits well with the need to delay sowing in Australia to reduce disease severity, as the delay gives annual weeds time to germinate and still be controlled by cultivation or nonselective herbicide before the crop is sown. The same applies to autumn and winter germinating weeds with spring sowing in North America and Europe. However, it is likely that more weeds will germinate with the crop in both systems, and pre-emergent herbicides are usually applied. Postemergent herbicides are also often necessary. They should be applied as early as is consistent with allowing weeds time to germinate. Early weed removal is important for maximizing grain yield (Figure 4). The weeds present and the growing environment determine how critical early removal is. Many postemergent herbicides cause crop damage if applied at the wrong growth stage of the crop, or if applied to a stressed crop. Rolling can cause enough stress for normally safe herbicides to cause unacceptable damage, and in Australia, it is recommended that no post-emergent herbicides are applied within 2 weeks of rolling. In the UK, a leaf wax test is used to assess the safety of some herbicides. It involves dipping plants in a solution of the dye crystal violet and observing how much dye adheres to the leaves. The less that adheres, the more wax is on the leaves, and the safer it is to apply herbicide.

Weeds germinating late in the life of the crop compete less strongly than early germinating weeds, and have less effect on grain yield. However, to minimize weed seed carryover into the next phase of the rotation, they should be controlled. In Australia "crop-topping" is commonly practiced. This involves spraying low rates of nonselective herbicide (usually paraquat) onto the maturing crop so that it disrupts maturation of weed seeds. Pea's early maturity is well suited to this practice, because the crop suffers little damage when weeds are at the right stage for maximum effect.

Disease Management

Pea is subject to many diseases. The most important fungal and bacterial diseases are described in Table 5. Pea is also affected by a large number of virus

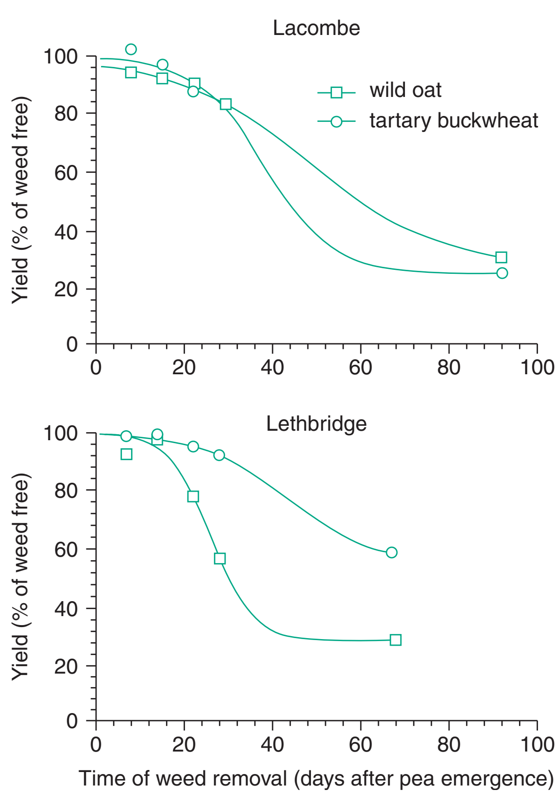

Figure 4 Effects of time of removal of wild oat and tartary buckwheat on pea grain yield loss for two sites in Alberta, Canada. Data are means of 3 trials at each site from 1996 to 1998. (Reproduced with permission from Harker KN, *et al.* (2001) *Weed technology* 15, 277–283.)

Table 5 Some of the more important fungal and bacterial diseases affecting pea

Disease	*Causal organism*	*Type of damage*	*Occurrence*	*Management*
Fungal diseases				
Damping off	*Pythium* spp.	Seed and seedling rot	All pea-growing regions	Fungicide seed dressing Use high vigor seed
Aphanomyces root rot	*Aphanomyces euteiches*	Root rot	North America, Europe	Avoid infested sites, rotation with oats
Fusarium root rot	*Fusarium solani* f. sp. *pisi*	Epicotyl, hypocotyl, and taproot rot	All pea-growing regions	Rotation
Blackspot, *Ascochyta* or *Mycosphaerella* blight	*Ascochyta pisi*, *Mycosphaerella pinodes*, *Phoma medicaginis*	Spotting or larger black lesions on leaves, stems and pods, footrot	All pea-growing regions	Fungicide seed dressings, foliar fungicide, rotation, delayed sowing
Downy mildew	*Peronospora viciae*	Fluffy lesions on lower leaf surfaces, or with systemic infection severely stunted plants that die before flowering	All pea-growing regions	Resistant cultivars, fungicide seed dressings, rotation, destruction of infected residue from previous crops
Powdery mildew	*Erysiphe pisi* (syn. *E. polygoni*)	White powdery lesions on upper leaf surfaces that can spread to stems and pods	All pea-growing regions	Resistant cultivars, foliar fungicide, rotation, destruction of infected residue from previous crops
Sclerotinia white mold	*Sclerotinia sclerotiorum*	Plants wilt and rapidly die Affected areas have a water-soaked appearance, and white fluffy growth may be seen, especially near soil surface	All pea-growing regions	Rotation, avoid growing in rotation with canola or oilseed rape
Fusarium wilt	*Fusarium oxysporum* f. sp. *Pisi*	Wilting and eventual death of plants	North America, Europe	Resistant cultivars, rotation
Bacterial diseases				
Bacterial blight	*Pseudomonas syringae* pv. *pisi* and *Pseudomonas syringae* pv. *syringae*	Water-soaked lesions on leaves, pods and stems that later become brown and necrotic	All pea-growing regions	Resistant cultivars, plant uninfected seed

Compiled from Kraft JM and Pfleger FL (eds.) (2001) *Compendium of Pea Diseases and Pests*, 2nd edn., 67pp. St. Paul, Minnesota, USA: APS Press; and Kaiser WJ, *et al.* (2000) Foliar diseases of cool season food legumes and their control. In: Knight R (ed.) *Linking Research and Marketing Opportunities for Pulses in the 21st Century*, Current Plant Science and Biotechnology in Agriculture, vol. 34, pp. 437–455. Dordrecht: Kluwer.

diseases, including alfalfa mosaic virus, bean leaf roll virus, bean yellow mosaic virus, cucumber mosaic virus, pea enation mosaic virus, and pea seedborne mosaic virus. Management consists of using virus-free seed (many viruses are seed borne), discouraging aphids (which spread many of these viruses within a crop) and using resistant cultivars. This article briefly describes some agronomic considerations in *Ascochyta/Mycosphaerella* blight management but for other diseases readers should refer to references provided.

***Ascochyta/Mycosphaerella* blight or black spot** This disease is found in all pea-producing areas of the world and can cause up to 75% yield loss. It is caused by a complex of three fungi – *Ascochyta pisi*, *Mycosphaerella pinodes*, and *Phoma medicaginis* – and symptoms included leaf, stem, and pod spotting, and foot rot. *M. pinodes* is the most widespread of the causal organisms, and the most damaging.

The causal fungi can be spread on the seed but, in Australia at least, seed transmission is a minor source of infection compared to spores released from the residue of previous crops, and fungi persisting in the soil. These spores can be carried several kilometers by wind and, once a crop is infected, current lesions act as a secondary source of spores for further spread.

Management of the disease consists of trying to minimize the risk of infection rather than controlling an infection that has begun. Seed can be tested for infection and treated with fungicide if excessive levels are found. Different pea-growing regions have

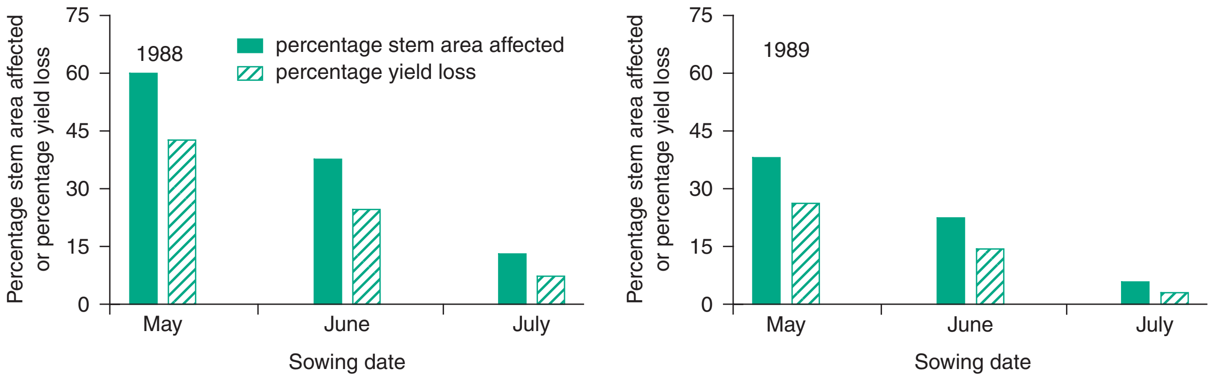

Figure 5 Effect of delaying sowing on percentage stem area of field pea affected by *Ascochyta* blight, and percentage grain yield loss relative to plots kept disease-free by weekly fungicide sprays at Horsham, Victoria, Australia in 1988 and 1989. Data are means for 15 pea cultivars. (Adapted from Bretag TW, *et al.* (1995) *Australian Journal of Experimental Agriculture* 35, 531–536.)

different threshold infection levels at which seed treatment becomes worthwhile. Crop rotation is an important tool in reducing infection from old crop residues. In most pea-growing regions, it is recommended that pea not be grown more often than once every 4 or 5 years. In Australia, it is also recommended that pea crops are no closer than 500 m to stubbles from any of the previous year's crops.

In Australia, delayed sowing reduces infection risk, and plays an important role in blackspot management. Spore release begins when old crop residues are wet by rain, and continued release depends on temperature. Usually, by early winter, spore release is declining and crops sown then develop little infection (Figure 5). In Western Australia, a computer model has been developed that takes all these factors into account and, when the locations of previous pea crops in an area and local weather data are provided, produces maps of blackspot risk for different sowing times.

Foliar fungicides can give effective control, but grain yield responses are not usually reliable enough to make them economically viable. Chlorothalonil is registered for *Mycosphaerella* control in Canada. There are also significant differences between cultivars in their susceptibility to *Ascochyta* and *Mycosphaerella*, but all existing cultivars suffer appreciable damage. Nevertheless, understanding of the genetics of tolerance to this disease is improving rapidly, and eventually good resistance should become available.

Invertebrate Pest Management

Pea is subject to many invertebrate pests, including insects, arthropods, and nematodes. Some of the more important insect, mollusc, and arthropod pests are listed in Table 6. Effective chemical control is possible for most of these pests, but agronomic management also influences how serious a problem many of them become. The interested reader should consult more specialized references given in the Further Reading section.

Harvesting

Pea is harvested with the same machinery (combine harvesters) as cereals. Picking up and feeding a lodged crop into the harvester has traditionally been the biggest challenge. While erect semileafless cultivars have gone a long way to overcome this problem in Europe and North America, attachments such as crop lifters, special pea pick-up fronts, and flexible cutter bars usually make the job easier. Rolling after sowing also helps by removing obstacles such as stones and soil clods that can cause considerable machinery damage if picked up with the crop. Swathing is an alternative to direct harvesting.

To maximize grain yield and quality, pea should be harvested at the right time. In Canada and Europe, this is when seed moisture falls to 20%, in Australia the recommended moisture content for harvest is 15%. It is likely that the crop will have some green tips at this stage, and perhaps some green pods as well. Grain harvested at this stage will need drying to avoid spoilage in storage. Often this can be achieved simply by circulating dry external air through the grain in silos. Even earlier harvesting can result in an unacceptable level of immature seed in the sample, and later harvesting in more severe lodging and hence greater difficulty picking up the crop, more insect damage (especially from the pea weevil, *Bruchus pisorum*), more shattering losses, and greater mechanical damage to the grain. Late harvesting also increases the risk of cotyledon bleaching in blue (green) and marrowfat pea. Desiccating crops approaching physiological maturity with diquat can

Table 6 Some of the more important invertebrate pests affecting pea

Common name	*Scientific name*	*Type of damage*	*Occurrence*
Seedling pests			
Wireworm	*Agriotes* spp., *Ctenicera* spp., *Limonius* spp., *Melanotus* spp.	Feeding on seed, and later on roots of emerged plants	North America, Europe
Cutworm and Armyworm	*Agrotis* spp., *Apamea* spp., *Euxoa* spp., *Peridroma* spp., *Pseudaletia* spp., *Sporodoptera* spp.	Feeding on emerged seedlings	All pea-growing regions
Red-legged earthmite	*Halotydeus destructor*	Feeding on emerged seedlings	Australia
Lucerne flea	*Sminthurus viridus*	Feeding on emerged seedlings	Australia
Slugs	*Deroceras reticulatum*, *Arion hortensis*	Feeding on leaves	Europe
Vegetative and reproductive pests			
Snails	*Helix* spp.	Feeding on leaves, contamination of grain	Europe, Australia
Pea aphid	*Acyrthosiphon pisum*	Feeding on stems and petioles, also flowers, pods, and leaves	All pea-growing regions
Bluegreen aphid	*Acyrthosiphon kondoi*	Feeding on growing point	Australia
Cowpea aphid	*Aphis craccivora*	Feeding on growing point	Australia
Thrips	*Thrips* spp. and *Frankliniella* spp.	Feeding on young leaves and growing points	All pea-growing regions
Pea leaf weevil (known in UK as pea weevil)	*Sitona lineatus*	Feeding on leaves and root nodules	North America and Europe
Reproductive pests			
Pea weevil	*Bruchus pisorum*	Feeding on developing seed, which may continue after harvest	Most pea-growing regions, not UK
Pea moth	*Cydia nigricanus*	Feeding on developing pods, and seeds	North America, Europe
Native budworm	*Helicoverpa punctigera* syn. *Heliothis punctigera*	Feeding on leaves, pods, and seeds	Australia
Lucerne seed web moth	*Etiella behrii*	Feeding on developing seeds	Australia

Compiled from Kraft JM and Pfleger FL (eds.) (2001) *Compendium of Pea Diseases and Pests*, 2nd edn., 67pp. St. Paul, Minnesota, USA: APS Press; Biddle AJ, *et al.* (1988) *The Pea Growing Handbook*, 6th edn., 264pp. Peterborough, UK: PGRO; and Carter JM (1999) *Field Pea Growers Guide*, 20pp. Melbourne, Australia: Agriculture Victoria.

assist achieving even maturation, and in accelerating maturation late in the season in North America and Europe. Desiccating with glyphosate is not recommended because it can reduce the viability of harvested seed.

Pea grain is fragile, especially at low moisture contents (below 14%). Luckily it threshes easily, so the drum or rotor speed should be as low as possible, and the concave closed only enough so that pods are threshed. Once it has been harvested the seed should be handled as gently, and as little, as possible to prevent further mechanical damage. Damage from too vigorous threshing and excessive handling includes split grain and reduced seed viability, but also microscopic cracks in the seedcoat, which reduce the vigor of viable seeds.

Introduction

Peanut (*Arachis hypogaea* L.) is a tropical legume grown over a diverse range of environmental conditions, with the main commercial production occurring in the northern hemisphere. Peanut is used widely throughout the world, being one of the principal oilseeds as well as a high-quality food for human consumption. Over the past five years, the crop has been grown on ~21 million hectares (Mha), with an annual production of ~30 million metric tons (Mt).

This article provides a brief overview of the peanut crop and concentrates on its unique features, which lead to its reputation as a high-value, high-quality, and extremely adaptable grain legume. The article provides information on aspects including its historical background, distribution, utilization and quality issues, morphology, breeding, and recent innovations in biotechnology, which offer some exciting prospects for increased productivity and improved quality. The article purposely concentrates on aspects that are of interest, and of relevant expertise, to the author.

Historical Background

Peanut (sometimes referred to as groundnut) and the genus *Arachis*, originated in central Brazil in South America. Early archaeological evidence suggests that peanut was domesticated in northern Argentina and eastern Bolivia, and subsequently grown in Mexico, the Caribbean Basin and throughout Brazil, and the coastal regions of Peru. It is believed that the crop did not reach other parts of the world until after Columbus arrived in America, after which time it was taken from Brazil to Africa and the Far East by the Portuguese. The Spaniards are believed to have taken the crop to the western Pacific, Indonesia, and China early in the sixteenth century.

Arachis hypogaea is an annual member of the family Papilionaceae, which shows a unique feature of maturing their fruits underground (Figure 1). The plant comprises a number of subspecies – *fastigiata* var. *fastigiata* (Valencia) and var. *vulgaris* (Spanish), both bunch forms; and subspecies *hypogaea* var. *hypogaea* (Virginia bunch and runner). Large

variations in growth habit (erect versus spreading), branching type (alternate or sequential), maturity (90–160 days), and traditional market types (Virginia, Spanish, or Valencia) exist. The present distribution of peanut covers from 40°S to 40°N in warmer growing regions of tropical, subtropical, and Mediterranean climates, where soils are light, neutral, or alkaline, and rainfall (plus irrigation) exceeds ~400 mm per season.

World Peanut Production and Utilization

Production and Yields

The world average nut-in-shell production was ~29 Mt during the period 1996–2000, and has been growing at an annual rate of 2.5% since 1970. While total world production has increased, there has been significant regional variation, with most of the growth occurring in Asia, followed by

Table 1 Annual peanut production and yields for the ten major world-producing countries during the periods 1972–75 and 1996–2000

Country	*Production 1972–75 ('000 Mt)*	*Production 1996–2000 ('000 Mt)*	*% Change since 1972–75*	*Average yield 1972–75 (kg ha^{-1})*	*Average yield 1996–2000 (kg ha^{-1})*	*% Change since 1972–75*
China	2 204	11 463	420	1.2	2.84	136

Africa and America. Most of the growth in Asia has been in China, with a dramatic increase of 420% between 1975 and 2000, which makes China the first ranking peanut producing nation (Table 1). This increase in production has been due to both increased area planted (nearly fourfold) and increased yields (more than doubled). These increases have been associated with recent market reforms encouraging greater areas of peanut production, as well as new technologies including plastic mulching, which have substantially improved yields. In India, most of the increase in production can be explained by the increase in the area, since yields have remained stable during the last 30 years. Production in the US has remained relatively static over the same period, with only minor changes in area grown and yields per ha. Yields in Africa remained relatively stable, although levels are only half that of more developed countries. The exception to this trend is Nigeria, the main west African producer, which showed a substantial improvement in yield over the past 30 years.

Utilization

Peanut is grown for its kernel, oil and meal derived from crushing kernels, as well as the vegetative residue (haulms). Nearly 50% of the world production is currently crushed for cooking oil, although large variations between countries exist. For example, India and Argentina crush ~90% of the production compared to countries such as Indonesia, Mexico, and Ghana who directly consume over 95% of the crop for food purposes. Over the past 30 years, there has been consistent increase in peanut used as a food crop, owing to its excellent nutritious makeup, being high in oil, protein, and carbohydrate. Peanut kernels can be consumed fresh, dry, boiled, or roasted. In developed countries such as the US, Europe, and Canada about half the production is used for peanut butter, with the remainder used for salted peanuts snacks and a range of confectionary products.

The peanut haulms are of a very high nutritional quality and are fed to cattle and other animals as a source of high protein. The shells of the mature pods can also be used as a fuel, a high-fiber filler in animal feeds, a mulch on gardens and more recently as a possible source for deactivated carbon production.

Trade

The world trade market for peanuts can be considered as a residual market, in that only a very small proportion of the world production is traded owing to most of the production being utilized domestically. While the average share of world peanut production exported over the past 30 years has remained constant at 5%, the total volume of exports has grown steadily from ~1.1 Mt in 1976 to 1.5 Mt in 2000. The three major exporters China, Argentina, and USA have comprised over 60% of the total world trade. The peanut trade has steadily shifted from a crush-for-oil to a market-for-food purpose and this has meant that there is a requirement now for higher quality peanuts, especially with low aflatoxin contamination (see below). Strict quality requirements necessitating that aflatoxin levels meet strict regulatory limits (e.g., <4 ppb total aflatoxins in European markets) have impeded a number of Asian (China, Vietnam, India) and African (Nigeria, Sudan) countries in competing in the edible peanut market. Indeed, high levels of aflatoxin in exported product forced the European Union to temporarily ban Chinese imports during 2002, and to enforce

legislation requiring stricter testing procedures at ports of entry.

Morphology and Growth Physiology

Being of indeterminate botanical type, peanut supports simultaneous growth of vegetative and reproductive structures, and so compete for nutrients and assimilate throughout most of the crop life cycle. Flowers first appear ~25–35 days after planting, depending on the maturity of the variety and the thermal environment under which the crop is grown, and continue to be produced until final maturity. The rate of flower initiation increases to a maximum and then declines as the pod load increases and the crop approaches maturity. Bursts of flowering are common after rain, following drought periods during the vegetative phase, and can lead to more synchronous pod set and higher yields and quality given favorable growing conditions during the pod-filling period. Peanut has a self-fertilized flower that withers soon after fertilization. Rates of natural outcrossing are low and have been estimated at between 0.7% and 2.5%. After 5–7 days, the base of the fertilized ovary (gynophore or peg) begins to elongate towards the soil, penetrating the soil up to a depth of 4–5 cm. The ovary then begins to swell and turns horizontally away from the plant (Figure 1), which takes between 15 and 20 days from the initial flowering event. The pod then expands rapidly until reaching full dimensions characteristic of the variety, with seed cotyledon growth over the next few weeks. Because of the slow rate of pod addition, many pods must be added and seeds initiated to form a full pod load on the plant. Pod growth rates vary depending on temperature, water status, varietal maturity, and partitioning ability.

Farming Systems

In most developed countries, peanut is grown as a sole crop under rainfed or irrigated conditions, using fully mechanized cultural practices, including large-scale mechanical planting, spraying (weeds and diseases), and harvesting equipment. Friable soils, including red ferrosols and lighter textured sands, are commonly selected to allow mechanised harvesting equipment to operate efficiently and minimize pod losses which can be significant on harder setting soils. In countries such as the USA and Australia, it is not uncommon for one farming family to farm 500 or more ha per annum. Peanuts are generally grown in a rotation of one peanut crop in two or three summer crops in order to minimize soil-borne diseases, use fertilizers more efficiently, and allow more effective weed control.

In developing countries throughout Asia and Africa, smaller scale peanut production on 1–2 ha plots is more common, under a variety of cropping systems. Peanut is renowned for its superior drought tolerance and is often grown in very marginal regions where other legume crops such as soybean and mung bean fail to produce grain. In regions such as India, peanut is often grown as "dual purpose" crop, where both kernels for a cash crop and haulms for animal fodder are produced in seasons with average to above-average rainfall, while only high-quality fodder are produced in severe drought years. Peanuts are important in rice-based sequential cropping systems throughout much of Asia. The crop is either planted with irrigation before a rice crop, or grown on residual soil moisture after the rice harvest.

Peanut is also commonly grown as an intercrop with longer season annual and perennial crops, including castor, cassava, cotton, and sugar. For example, in India considerable yield per ha advantages of up to 65% have been demonstrated, when using 6–8 rows of peanut to a single row of pigeon pea. Peanut can be grown underneath perennial tree canopies such as coconut, cocoa, oil palm, and rubber, owing to its effective shade tolerance. Under these systems, as well as providing biologically fixed nitrogen, peanut can provide cash income until the plantation trees are old enough to produce their end products.

Biotic and Abiotic Constraints to Yield

Insect Pests

Around 360 species of arthropod pests are known to attack peanuts before harvest in different regions of the world. In general, the foliage pests are of lesser importance than the soil-inhabiting pests, which can cause direct economic damage to pods. A large number of thrips species are however known to attack peanut and have become very important vectors of some of the debilitating peanut viruses such as tomato spotted wilt virus (TSWV). The most important soil-borne pests in the developed world are the lesser corn stalk borer, *Elasmopalpus lignosellus*, and white grubs, the larvae of which attack pegs and pods and cause substantial economic damage. These insects also cause pod damage, which can lead to aflatoxin contamination in kernels following infection via the fungus *Aspergillus flavus*.

Fungal Pests

The most important fungi causing economic damage to peanut crops around the world are the leaf spots

(early and late) and leaf rust. These diseases cause leaf necrosis and can lead to severe yield losses if not effectively controlled by fungicides. A number of highly efficient chemical formulations have been developed over recent years to control both diseases, hence effective control can be achieved when using a rigorous spray program aimed at optimizing chemical efficacy and inoculum load. Genetic resistance is available, however there is a known negative association between foliar disease resistance and yield potential.

A number of soil-borne diseases can cause significant economic losses in peanuts, via seedling and plant death, as well as via direct pod damage due to pod rots. The most important diseases include white mold (*Sclerotium rolfsii*), *Cylindrocladium* black rot (CBR), and *Sclerotinia* blight.

Viruses

Many viruses infect peanut and historically they have not caused widespread economic losses. This situation has changed over the past decade or so, with the arrival of the potyvirus peanut stripe virus (PStV) in Asia and the USA, and TSWV in the USA. Both these viruses have caused significant yield losses and are threatening the viability of peanut production in specific regions. A system of cultural practices has been implemented to control these diseases, including planting date and plant and row spacings to control thrip vectors such as the western flower thrip. Some genetic tolerance has been identified for TSWV in the USA, although total immunity has not been developed and there is evidence of a breakdown in this resistance. There is no known genetic resistance to PStV, although a recent collaborative project involving Australian, Indonesian, and Chinese scientists has developed resistant breeding lines using a transgenic coat protein mediated resistance approach.

Water Stress

The major effect of soil and crop water deficits on peanut productivity relates to deceases in canopy coverage, pod initiation, and conversion into viable pods and ultimately on pod yield. Peanut has a reputation of being an extremely drought tolerant crop, which is associated with a number of important traits, including its ability to withstand very low relative leaf-water contents (e.g., 29%), deep-rooting habit and indeterminate reproductive system which gives enormous plasticity in rainfed environments typified by intermittent and end-of-season patterns of drought stress. Significant genetic variation in these traits exists and breeding programs aimed at incorporating these traits in combination are currently underway to further enhance peanut drought resistance.

Table 2 Depth of peg penetration (mm) as a function of penetrometer resistance (MPa) in the surface 1.5 cm of soil during a 21 day pegging period for peanut plants (cvs. Robut 33-1 and McCubbin) grown in pots

	Penetrometer resistance in surface 1.5 cm of soil (MPa)							
Cultivar	0.5	1.0	2.0	3.0	4.0	5.0	6.0	7.0
Robut 33-1	43	39	12	9	6	5	5	5
McCubbin	60	50	14	9	5	4	5	5

Peanut can be particularly susceptible to drought stress during the early reproductive stage, as soil water deficits then can influence peg and pod development through direct effects on plant water status and assimilate supply, or through effects on peg penetration and calcium uptake in dry surface soils. Peg entry and pod development are extremely sensitive to soil hardness, which often increases with decreasing soil water content. Table 2 illustrates that the depth of peg penetration (and subsequent pod growth) in two peanut cultivars declines linearly as soil strength (as measured by penetrometer resistance), increased from 0.1 to 2.0 MPa, with cessation of peg growth above 2.0 MPa.

Nutritional Constraints

As for most crops, peanut requires an adequate supply of each essential element during the growing season for maximum growth.

The specific nutritional issues of most importance for peanut production include calcium (Ca) and biologically fixed nitrogen (BFN). It has been well documented that low soil-water content in the podding zone can decrease Ca uptake and induce Ca deficiency in peanut and lead to abortion of developing seeds, leading to empty pods, referred to as "pops." In aerial fruiting plants, Ca is absorbed by roots and transported via the transpiration stream (xylem) to the developing pod, and is highly immobile in the phloem of the plant. As the pegs and pods of the peanut plant do not transpire, Ca cannot be translocated from the root to the developing pod, and hence pods rely on their Ca requirement via direct absorption through pods from the soil solution. Calcium, usually applied as gypsum, has been widely used to increase the yield of peanut under drought conditions occurring during early pod set. Large seeded Virginia types have also been shown to be more sensitive to drought-induced Ca deficiency than smaller seeded Spanish types.

Peanuts have a very effective BNF system and are promiscuously nodulated by strains of rhizobium of the cowpea miscellany group. Inoculation of seeds with effective rhizobia have led to substantial increases in peanut yield in fields, which have not

previously grown peanuts. It is generally accepted that once a field has successfully grown a peanut crop, it should not require future rhizobium applications. Estimates of fixed nitrogen as large as $300\,\mathrm{kg\,N\,ha^{-1}}$ have been reported for well-watered crops, with reports that BNF can supply over 80% of the plants total N uptake. Although most of the N in the crop is removed when the pods are harvested, numerous experiments have shown that significant N may be left in the soil for uptake by subsequent crops.

Light and Temperature

While growth and yield of peanut are known to be linearly related to total solar radiation receipt, recent data have shown that reproductive development can be strongly related to photoperiod (day-length) in sensitive cultivars. Peanuts were previously thought to be day-neutral, with phenology mainly driven by temperature. Controlled environment and field experiments have since determined that reproductive efficiency (i.e., cumulative flowering, peg and pod number, and allocation of dry matter to pods) after flowering can be modified considerably by varying photoperiod. The response has been characterized as quantitative short-day to day-neutral, with apparent variation among cultivars. More recent data has also discovered that significant photo-thermal interactions in this response exist in peanut, with the sensitivity of reproductive efficiency increasing at higher temperatures (e.g., mean daily temperatures exceeding 26°C).

Peanut is known to grow well under a wide range of temperatures, with daily optima for the rate of development, growth processes, and yield being ~25°C to 30°C. High temperatures in excess of 35°C can reduce leaf area development, reduce the number of pods and result in lowered harvest indices and yields.

Quality, Nutritional, and Food Safety Issues

Nutritional Aspects

Peanuts are an excellent source of nutrition for both humans and animals. Table 3 gives a proximate composition of peanut kernels, and clearly shows that they are a rich source of protein, oil, carbohydrate, and minerals. Peanuts are also a good source of niacin, folic acid, phosphorous, vitamin E, and phytosterols.

Peanuts are consumed as oil, whole as snacks, in confectionaries, and peanut butter. As a human food, they are often roasted before use, which accentuates the nutty flavor that contributes to consumer acceptance. Nearly two-thirds of the world production of peanuts are crushed and utilized as high-quality oil, making it one of the world's leading oil crops.

Table 3 Proximate composition of peanut kernels

Product	*% Composition*
Moisture	5.0
Protein	30.0
Oil	48.0
Carbohydrate	15.5
Crude fiber	3.0
Ash	2.0

Peanut oil is mostly composed of triglycerides of eight fatty acids. Around 80% of these fatty acids are either oleic acid (monounsaturated, C 18:1) or linoleic acid (polyunsaturated, C 18:2). Generally, these two fatty acids vary inversely. Of the eight commonly detectable fatty acids in peanut oil, linoleic is the only one that is polyunsaturated. The second double bond in a linoleic acid molecule renders it far more susceptible to oxidation. This "oxidative rancidity" generates off-flavors in peanut products, and hence limits the shelf life of products in retail outlets. The monounsaturated oil type in peanuts is also known to be "heart healthy." Recent studies in the USA have shown that peanuts and peanut butter lowered blood cholesterol levels as effectively as olive oil in moderate fat diets. It was also found that diets including peanuts and peanut butter lowered cardiovascular disease risk by 21%, whereas the low-fat diet decreased the risk by only 12%.

In the late 1980s, researchers at the University of Florida discovered a (naturally occurring) mutant peanut plant with over 75% oleic acid, and linoleic acid below 5% of fatty acids, which they subsequently described as "high oleic" germplasm. This trait has recently been bred into adapted commercial varieties, which are currently being released in the USA and Australia. This characteristic will provide even greater benefits to both product shelf life and human health. The increased shelf life is best illustrated by the peroxide value (a measure of shelf life) data shown in Figure 2, which shows how high oleic peanuts maintain low PV's (and hence no rancid off-flavors) during an accelerated aging test.

Food Safety Issues

Aflatoxin Aflatoxin is a human carcinogen that contaminates peanuts, particularly under end-of-season drought and makes them unsafe for human consumption. Aflatoxin production occurs in peanut kernels particularly under drought conditions consequent to infection by *Aspergillus flavus* and *A. parasiticus*. The "within-season" seed infection by the fungi is also responsible for aflatoxin production depending on

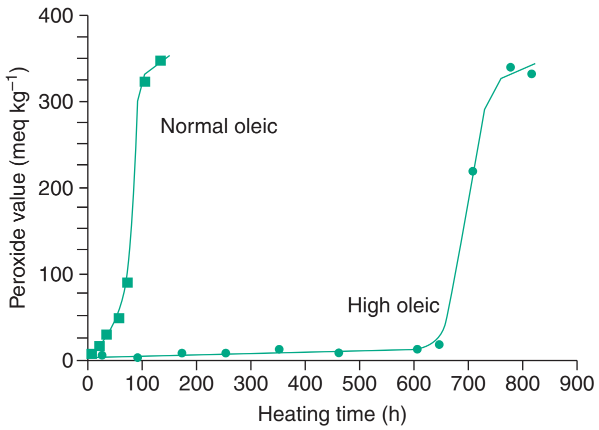

Figure 2 Peroxide value over time as a measure of oxidation of high and low oleic peanut oils. (Reproduced with permission from O'Keefe, Wiley, and Knauft (1993) *Journal American Oil Chemists Society* 70: 489–492.)

the conditions during the postharvest-drying phase in the field, or during storage conditions.

The aflatoxin problem is a worldwide phenomenon, but is particularly severe in developing countries in Africa, South, and Southeast Asia, where food safety and security systems are not well developed to protect consumers against unsafe food products. There is a very low level of awareness about impacts of aflatoxin contamination on human/livestock, particularly in peanut-producing countries of the semiarid tropics, and hence the source of contamination remains invisible and its effects and potential impacts on human and livestock health are not well documented. The human impact, in terms of mortality and morbidity, in peanut-growing countries in the developing world is enormous, with estimates of up to 20 000 deaths per year arising from aflatoxin-related illnesses being made in some Southeast Asian countries. In more developed countries, consumers are more aware of food safety issues such as aflatoxin, and are increasingly demanding peanut products meet strict regulatory standards. Current strategies to reduce aflatoxin levels to below regulatory limits (e.g., 15 parts per billion (ppb) in retail products in the USA and Australia) involve a post-farm-gate process of selective segregation achieved through blanching and color sorting in shelling plants. This strategy, although effective, is time-consuming, wasteful, and consequently, very expensive. These costs are continually passed onto growers and hence, threaten the viability of peanut farming in rainfed-production systems. In developing countries, aflatoxin regulatory limits for peanut have been stringently applied and have recently affected export of peanut and its products (see above).

A number of potential solutions have been proposed to minimize aflatoxin at its source, the farm. Use of agronomic management methods, including pre- and postharvest strategies that minimize aflatoxin contamination by the fungus *Aspergillus flavus/parasiticus* have shown to be effective. A number of peanut varieties have been shown to have some aflatoxin tolerance, which seems to be associated with drought avoidance and escape mechanisms. Recent research is also investigating the potential for using a biocontrol approach, where nontoxigenic strains of the *Aspergillus flavus* fungus are applied to the soil, and infect kernels and hence competitively exclude toxigenic strains.

Cadmium Cadmium (Cd) is a heavy metal, which can accumulate in foods such as peanut and potentially lead to kidney damage if high levels of intake occur over prolonged periods. Recent research has shown that peanut can accumulate high Cd levels on acidic sandy soils, especially where there has been a history of phosphatic fertilizer application, which had contained Cd as a by-product. Developed countries have begun to apply strict regulatory standards, which have recently affected some peanut exporting nations. A number of management practices have been proposed to minimize Cd accumulation in peanuts and readers are referred to the website listed at the end.

Anaphylaxis Anaphylaxis is a sudden, severe, potentially fatal, systemic allergic reaction to peanuts that can involve various areas of the body (such as the skin, respiratory tract, gastrointestinal tract, and cardiovascular system). Symptoms occur within minutes to 2 h after contact with the allergy-causing substance, but in rare instances may occur up to 4 h later. Anaphylactic reactions can be mild to life-threatening, and seem to have an annual incidence of ~30 per 100 000 persons. The best treatment currently is avoidance of peanuts and peanut products. Medical researchers are working on developing treatments, such as vaccination, to prevent or decrease the symptoms of serious food allergy to peanut consumption. Before developing such treatments, it is necessary first to identify the specific proteins that are responsible for triggering the allergic response. A number of the proteins responsible for peanut allergy have already been identified. Medical treatments to desensitize or minimize peanut and other food allergy reactions are under development, but will not be widely available for several years.

Breeding and Biotechnology

The primary objectives of most peanut-breeding programs are to develop high-yield potential, resistance to local environmental, and disease stresses in conjunction with broad or specific adaptation to the appropriate cropping system. As peanuts are grown under a variety of agro-ecological systems, local breeding objectives will undoubtedly change between regions. Once general adaptation and disease resistances have been developed, breeding efforts in the more developed countries have tended to concentrate on quality issues such as improved flavor, high oleic oil, blanchability, and kernel size.

There is enormous genetic variability available for most traits of interest, including host-plant resistance to disease and insects and along with important agronomic and quality traits. This germplasm has been collected and preserved thanks to the extensive collections made in South America during the early to mid-1900s. The most significant collection is housed at the International Crops Research Institute for the Semi-Arid Tropics (ICRISAT) in India, where some 12 000 accessions are maintained, along with more than 70 wild *Arachis* species.

The most common breeding approach used by peanut breeders is the pedigree method, which allows selection for highly heritable traits in early generations. Generally, plant and pod type are the focus of this selection, which allows progeny numbers to be rapidly culled, after which emphasis can be placed in later generations on quantitative characters such as yield and quality traits. Backcross breeding has not been used widely in peanut owing to the lack of simply inherited traits for disease and insect resistance. The technique is however being used widely in the USA and Australia to backcross the single gene high oleic trait.

The biotechnology revolution occurring in a range of important crop plants has yet to be realized in peanut. This has been largely due to the lack of polymorphism for allozymes or restriction fragment length polymorphisms (RFLPs), which has restricted the use of marker technology for improved selection of quantitative traits such as yield. Several research institutions have been able to transform peanut with exogenous DNA and generate fertile plants from transformed tissues. This technology has opened up enormous possibilities for expanding the genetic diversity of peanut. Recent applications of this technology include genetic transformation for disease resistance to PStV and TSWV.

PET FOODS

R C E Guy, Campden and Chorleywood Food Research Association, Chipping Campden, UK

Introduction

What Are Pet Foods?

Pet foods have been manufactured since the 1940s in the USA and Europe, and today there are manufacturing plants in most developed countries. They originated from animal feedstuffs based on nutrition that were manufactured for livestock. The close relationship between pets and owners led to the development of certain sensory requirements to attract the consumer. The products were made with more attractive shapes and colors to satisfy the owners and with special flavorings to ensure that the animals were happy. However, the core products are nutritionally well balanced to give a complete diet for an animal so that they can live a healthy life if fed only on the pet food.

There are also some special products known as "treats" that may be more highly flavored, or have a special chewy texture. These products are aimed at providing an enjoyable experience for the animal and its owner, and are not necessarily so well balanced nutritionally.

There are many types of pets in the modern world, but cats and dogs dominate all the production in the pet food market by a large margin with sales of over five billion pounds worldwide. The next levels of pet foods are for fish, small mammals such as rabbits, guinea pigs, and ferrets, birds, and then the products begin to merge with animal feeds for farm animals and reptiles. In this article only the products made for cats and dogs are described in detail, and some of the products made for fish and small mammals are briefly mentioned.

Types of Foods

The manufacture of pet has taken two main forms in the past century; these may be described as wet and dry types. Using the mature UK market as an example, the proportions of each type of product sold in 2001 are shown in Table 1. Wet pet foods were developed originally as canned products that had moisture contents of 65–70% w/w, similar to cooked meat and gravy, or raw meat. They could be used straight from the tin and were easily digested by the animals. In the retail market, cans were sold mainly in 400 and 800 g sizes. These were satisfactory for cats and small dogs, but were a little small for large dogs. The packs of cans became very heavy and new forms were developed, such as the intermediate-moisture products with much less water (20–30% compared with 65–70% w/w for cans) that could be sold in large plastic tubes. The food could be easily sliced from the roll to provide the meals. However, they were not very successful and it was the dry products, with moisture content of ~10% that were preferred as the main alternative to canned pet foods.

More recently, laminated plastic and foil pouches have been introduced with individual meals that are lighter than cans but offer the same types of wet pet foods. In the market for cats they have captured 20% of the wet sales.

Initially dry products were developed as biscuits that could be added to supplement meals prepared at home. These might have been made up of meat and bones from the butcher, or the scraps from a family meal. However, with the advent of the new technology of extrusion cooking, it became possible to prepare a dry food from a well-balanced range of ingredients and was a complete meal. This new type of dry food had considerable advantages in weight for the shopper, removing 60% of the water in canned products plus the tin. The remaining dry solids, which were sold in paper or laminated plastic sacks had a long shelf life and were liked by the pets. Therefore, they began to replace the wet foods in several markets. However, the wet foods were still preferred by many customers for other reasons that the successful introduction of the small individual meal pouches of wet foods has helped to maintain market share for this form of pet food.

For other animals such as fish and small mammals most foods are sold as dry foods, except for some intermediate moisture products for fish. The dry products may be in the form of flakes, extruded rods or

Table 1 UK market for different types of pet foods 2001

pellets, and simple mixtures of different forms of grains, pellets, and flakes.

Dry Pet foods

Biscuit Technology

Two manufacturing processes are used for dry pet foods, traditional biscuit-making technology or extrusion cooking. Originally, biscuit making was developed by transferring knowledge from the bakery industry. Basic equipment was available to mix, sheet and cut out the shapes, and bake dough into a dry biscuit texture. In some cases, the dough was sheeted by forming extrusions with wide fan-shaped slit dies to produce a sheet, rather than rollers. In most processes the waste dough and biscuit material was added back into the mixer to form the new dough.

The recipes for the biscuits were largely cereal-based products (Table 2) with a small addition of meat, fat, and bone meal to provide flavor rather than nutrition. Some of the doughs were also allowed to ferment overnight (e.g., cracker doughs) to develop flavor, but generally they were mixed and allowed to stand for $\sim$2 h.

The dough produced by mixing the above recipes with water at a low level of 20–30% w/w was often stiff and crumbly, which could be sheeted out by extrusion and cut to form the biscuit shapes. These were usually simple geometric forms such as ovals and squares, but could also be formed into the well-known bone shape. After the pieces were shaped, the baking process was set up to give some aeration to the dough structure by rapid vapor creation, and then to dry out the biscuit to create their hard texture and color. This was not easy to achieve for dog biscuits, because of their size and the time available in the oven. Generally, biscuits were baked with a dry outer region and a moister center that would equilibrate with dry regions over several days, to give an average moisture <10% w/w (Figure 1). At this moisture level, the starchy structure would have a crunchy texture and good shelf life in the packs. Occasionally, this baking method caused problems because of the stresses created in the biscuits. The products could crack along lines of weakness and the biscuits could break into two or more pieces.

The traditional dog biscuit had a limited scope for development because of the long baking process. It also had other shortcomings, in that it had a fairly slow production rate and occupied a large factory area. Therefore, the development of extrusion cooking as an alternative method for dry pet-food production seized the imagination of manufacturers worldwide.

Table 2 Recipes for dog biscuits

Ingredients	%	%	%
Wheat flour	50.7	31.3	71.5

Yeast	0.7	0	0.1

Extrusion Cooking Technology

Extrusion cookers were invented in the 1940s to manufacture snacks from maize grits, but by the 1950s they were being adapted for the production of pet foods. At first the machinery was fairly crude and not well understood, and had a relatively small throughput of a few 100 kg h^{-1}. The recipes were still based on a high level of cereals, such as wheat and maize. Later, they were enriched with proteins from meat meals and soy meal and flour (Figure 2 and Table 3).

The potential that could be envisaged for extrusion cooking provided the driving force for its development, and the equipment manufacturers strove to meet the needs of the pet food industry. Extrusion cookers are continuous processing units that transform a dry mix feedstock into a plastic fluid with the addition of 10–20% w/w of water, within their barrels. This fluid can be shaped and expanded from the dies at the end of the machine and cut into pieces with a rotating knife.

Figure 1 Baked biscuits.

The benefits of using extruders, compared with biscuit technologies, were as follows:

- continuous processing with low manpower requirements;
- small factory space;
- range of shapes and sizes created with different dies;
- low moisture process to reduce energy in drying (baking);
- sterile products;
- short residence time for control of thermal history of materials; and
- efficient processing.

The improvements in manufacturing units and understanding of the process by operators have both been enormous since the 1960s with production rates doubling every 10 years or so, to reach an amazing 5–10 ton per hour ($t\,h^{-1}$) on the best modern plant.

Extrusion cooking – raw materials The basic process starts with the recipe and its components. These are selected for the qualities of flavor and nutrition, their interaction in the process, and their price. In all extrusion cooking processes, the raw materials interact with the processing variables of screw design, rotational speed, barrel temperature, die dimensions, and feed inputs to create the system variables within the machines and eventually the product characteristics of the extrudate. This complex multivariate process was difficult to study in the early machines because they were sealed systems. It was only in the 1980s that CCFRA with its split barrel APV MPF 50 twin screw machine was able to provide good information on the processing of cereals.

Figure 2 Extruded dry dog food.

Table 3 Recipe for extruded dog food

Bone and Meat meal	17%
Premixes	1%
Fats	5%

Most dry pet foods are based on the transformation of starch by a combination of high temperature and powerful shearing forces into a dispersed polymer fluid. Therefore, the starch content of a recipe is very important in determining the physical characteristics of the extruded products. All raw materials have some effect in the process and they may be viewed in terms of their potential in an extrusion process using Guy's classification system (Table 4).

The development of the current understanding of the role of raw material components on the transformation of starch and the extrusion and expansion phenomena at the die has led a diverse range of products and greater control of their quality.

There is one problem with dry extruded pet foods because of the starch content. Cats in particular are not suited to a starch-rich diet and they have problems with the digestion of starch. Generally, the pet foods are made in dense form with a low degree of cooking, or dispersion of granular starch.

Extrusion machinery – preconditioning The powder mix for the extrusion cooking process can be metered directly into the extruder barrel and processed without difficulty. However, the extruder manufacturers have developed a secondary unit to warm the powders and to add water and fats prior to processing in the main barrel. This additional treatment has been shown to increase processing rates and reduce energy and wear costs. Little or no gelatinization of the starch occurs in these units because they operate at $<100\,°C$ and the moisture being usually $<30\%$ w/w is too low to reach the melting temperature, T_m, for starch.

Table 4 Guy's classification system for ingredients by their functional effects in extrusion cooking

Number	*Functional group*	*Typical examples*
1	Structure forming	Starch, soy, and gluten
2	Dispersed phase fillers	Soy, bran, and uncooked starch
3	Plasticizer/lubricants	Water and oils
4	Soluble solids	Sugars, dextrins, salt
5	Nucleants	Calcium phosphates and carbonates, fibers
6	Coloring materials	Added and Maillard reactants
7	Flavoring materials	Added and Maillard reactants

Extrusion machinery – extrusion cookers The heart of the process is an extrusion cooker where the recipe is transformed and prepared for forming into products as it is extruded. M. Riaz describes the various types of extruders, including single and twin screw designs that are available in the market and explains the differences between various types. There have been at least 30 companies selling machines in the market worldwide, but today one or two large single screw machines and three large twin screw machines dominate the world markets.

In all these extruders the moist mix of powder and water is compressed and sheared so that it becomes hot enough (120–160°C) to melt the crystalline structures within native starch granules. Once softened, the starch granules are partly dispersed by the shearing action of the screws or paddle elements in the machine, to give an expandable cell-wall material for gas bubble expansion at the die exit. The differences in commercial machines depend on their production capacity and their ability to control the process in terms of the temperature and the degree of starch dispersion.

In pet foods, the starch dispersion is relatively low after the melting of starch has been achieved. This gives a fairly dense extrudate with an expansion of 1.5–2 ml g^{-1} specific volume for the extrudate. The ideal extruder is one with a short residence time in the hot shearing zone and a variable speed screw, which operates independently of the throughput rate at the lowest possible moisture. This type of extruder can be set to disperse starch to the required level at the lowest temperature and fastest throughput. Most extruders offer a compromise between these ideals and running costs, but the latest machines appear to offer more benefits and efficiency than the older models.

Extrusion machinery – coating and drying Once cut, the extrudate can be coated by spraying with a gravy and then dried in a moving or fluidized bed to its final moisture content of <10% w/w. The size of the dryer is dependent on the throughput and the moisture level, which may vary from 18% to 30% at the die exit, according to the process and the extruder.

Wet Pet Foods

The basic concept for wet pet food is a plate of meaty chunks surrounded by a meaty gravy or jelly. In practice, the meaty chunks may be made from reformed meat meals or vegetable proteins, such as soy or wheat gluten, or mixtures of both. The gravy is carefully thickened with gums and starches to control its physical character, both when hot and cold. Methods for forming the chunks have changed during the 1990s and now include the use of extrusion cooking to texturize proteins, and simpler thermal methods to gelatinization of starch within meat slurry.

Formation of Meat Chunks – Extrusion Cooking

The earliest method for the economic production of meat chunks was the texturization of soy flour by extrusion cooking. In this process the protein is hydrated to 35–40% moisture w/w and heated to 160°C in a high shear field to produce a fluid melt, similar to the polymer melt of starch developed in dry extrusion cooking. Soy proteins have a tendency to aggregate when denatured and disrupted by heating above their denaturation points of 75–100°C. The use of high shear fields in the extruder prevents this from occurring until they are pumped into the die channels. In long die channels, laminar flow can occur at the normal flow rates with only small shearing forces. This allows the protein molecules to align and form hydrogen and hydrophobic bonds to create layers of fibrous material not unlike meat fibers.

The extrusion through the die channels is usually at 120–140°C, and at the exit some water vapor evaporates from the matrix to open up the texture and leave an alveolar structure in the chunks that are cut at the die.

Texturized vegetable protein (TVP) can be made with a minimum of 45% soy protein, but becomes stronger and tougher with increasing protein levels up to 90%. The material made from flours or concentrates is satisfactory for pet foods and can carry other materials within its continuous phase. Generally, some starch is used to form a dispersed phase within the smooth continuum of the protein. Other proteins and meals can also be added to enrich the chunks that too will be dispersed in the main soy protein phase.

If the secondary protein becomes dominant in the recipe, it may replace the soy as the continuum. Thus, when wheat gluten is used at 40–50% of a mixture, it may become the continuous phase. This protein has been used extensively in chunks for cat food because cats prefer it to soy products.

In the development of texturized proteins, a new type of process has been developed by Clextral of Firminy in France. This process is based on the use of higher moisture (60–80%) in the melt and a long cool die in which the proteins are allowed more time to form their fibrous structure without evaporation of water vapor to disrupt them.

Formation of Meat Chunks – Thermal Gelling of Starch

In this process, wheat flours or other cereal flours are mixed into meat slurry to form a paste. The wheat

proteins hydrate to provide sufficient viscosity to help keep the solids in suspension until the paste is heated to gelatinize the starch granule of the flour. At this point the slurry becomes a solid gel whose strength increases on cooling and can be cut into small slices or chunks as required. This simple process may be carried out with special equipment to make it more efficient. In a continuous process the slurry is pumped through a forming tube, which is heated to warm the slurry and eventually gel the starch before it is extruded and cut.

This type of product and the texturized protein chunk must be stable in a canning process where the chunk is heated in gravy to 110–120°C for a period of 15–20 min. It was shown by that soy proteins must have a well-texturized protein structure to survive. In starch systems the presence of retrograded starch and some cross-linking may help the granules to retain the structure of the chunks.

Intermediate Moisture Products

The final type of wet cat and dog food was developed as a long-life product that could be stored at ambient temperatures and packed in light plastic bags or sleeves. Normally, a wet product will decay and be spoiled by microbiological growth once it has been removed from its can or pouch. However, if the water activity is reduced to <0.7 with a low pH of 4–5 and the product is pasteurized, it will remain in good condition for several months. It can be sold in plastic packs in normal retail outlets at ambient temperatures, alongside the dry and canned pet-food products (Table 5).

Treats and Other Foods

This section covers a set of products generally called "treats" and some other dry foods. Treats may be made in many forms but are usually dry products that for dogs can be carried by the owner and dispensed to the animals during their walk. The products may take the form of chewy leathery items, or individual biscuits can be made into bone shapes or produced by co-extrusion as mini-beefsteaks or "marrow" filled bones. The extrusion cooking units are very well suited to producing interesting shapes and being able to use special recipes to manufacture tasty products. For cats the treats are given in the house or garden. Again, one relies on special shapes and colors to please the owners, and on strong flavors and crunchy textures to satisfy the pet.

For the other pets that are kept in the home, the foods are not so well defined and are made as animal feedstuffs, with less thought about shape and color and more on nutrition and wholesome character. Some foods may be shaped into pellets by a forming extruder or pelleting press and some may be flaked as grain by flaking rolls or shaped as wet flour slurry on a roller dryer. The last mentioned method is used for the thin flakes fed to pet fish.

To summarize, it can be seen that the pet-food industry is dynamic and full of invention to increase efficiency and improve its products. The market has grown at a fast rate since the 1990s and there appears to an overall increase in the pet population with a slight movement toward cats instead of dogs.

Table 5 Intermediate moisture products

Ingredients	%
Poultry meal	32.0
Maize	17.8
Maize gluten	10.0
Soybean meal	8.0
Corn syrup/beet fiber	12.0
Beet fiber	4.0
Potassium sorbate	0.2
Propylene glycol	8.0
Phosphoric acid	2.0
Vitamin/mineral mix	3.0
Fats	3.0

Diseases and Pests

S A Barton, Oxford Agricultural Trials Ltd., Oxford, UK

Introduction

The importance of diseases and pests in terms of food crops provides a context that all can relate to. In order to recognize the symptoms caused by pathogenic fungi and bacteria, viruses, and other plant pests, it is necessary to be familiar with the way in which healthy plants appear and how they behave. It is in this vein that a reminder of general plant physiology is given, and the vulnerable stages in plant development and growth are highlighted. An element of detective work is often necessary when identifying the cause behind plant abnormalities; the results of attack by various types of pests can appear very similar to the effects of nutrient deficiencies. "Cereal," "combinable," or "grain" crops are terms used to include those that are grown to produce seed for human consumption, that can be harvested with a combine and have small, hard seeds. Barley, maize (corn), millet, oats, rice, rye, sorghum, triticale, and wheat are monocotyledonous and have a growing point at ground level (Figure 1a). The dicotyledonous plants including amaranth, beans, buckwheat, canola (oilseed rape), chickpeas, cotton, lentils, linola/linseed, lupins, peas, peanuts, quinoa, safflower, soybeans, and sunflowers have growing points aboveground level (Figure 1b). How these two types of plants grow, and in general this varies from plants to plants, determines their susceptibility to the various pests and diseases. An introduction to both infection and infestation of plants from pathogens and pests, respectively, is provided. Approaches to disease and pest management using both natural and man-made remedies are given. Some crop species are more resistant to attack (whether from grazing animals or microscopic pathogens), whilst others can only survive under sheltered conditions.

Importance of Diseases and Pests

The term "importance" is usually associated with positive attributes, e.g., "an important crop is one that has many uses." Detrimental factors are equally important, however, as they can have a huge, negative impact. Plants are dependent upon their environment; they require available nutrients, water, and sunlight in sufficient quantities to allow them to grow. If disease or pest damage occurs, normal plant function is

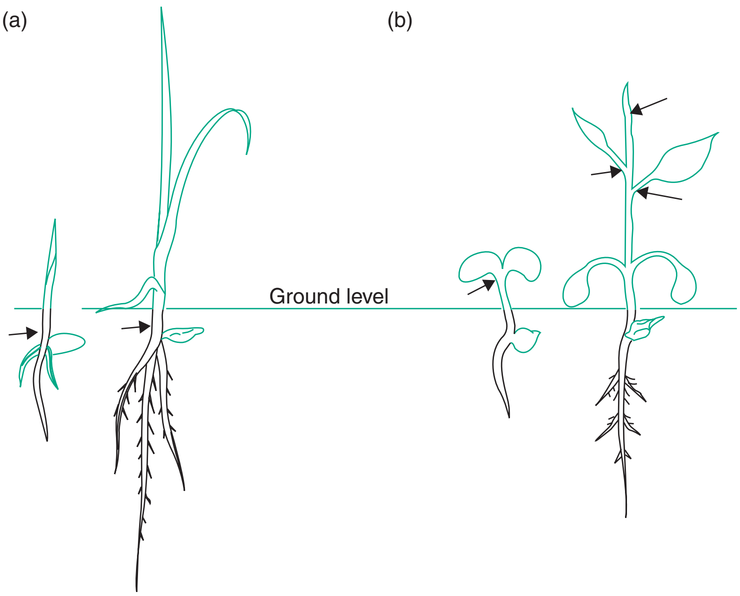

Figure 1 Location of plant growth points (arrows): (a) monocotyledons and (b) dicotyledons.

reduced, leading to injury or death unless the disease or pest is managed.

Fit for Purpose

The main effect of diseases and pests that occur in crop plants is to reduce the yield. For profitable food producers, the main concern from pests and diseases is the effect they have on the marketability of the crop. Often, if either yield or quality is reduced, at least the crop can still be sold, even if it is for a lower price than planned. If both factors are reduced, the crop will not be profitable at all. If this is the case for more than a season or two, such losses are unlikely to be sustainable. If a crop does not make money, there is no economic sense in growing it. When crops are grown to sell in niche markets, they must be fit for the purpose, as with organic produce. In this case, the way in which the crop is grown must meet certain, strict specifications throughout the growing season in order to retain its status. Part of the requirement in this example is not to use the majority of chemical pesticides (including fungicides) even when the crop is under attack. For the organic producer, not treating could mean reduced quality of produce, but treating could mean losing organic status and not being able to sell at the premium rate. Where market demand is present and there is fierce competition for a share, high standards of food quality and safety are vital.

Food Safety

The safety of food has become increasingly important over the years; besides affecting the marketability of a crop, it can have serious implications on consumer health. Pests and diseases can have a direct effect on the safety of food crops, such as the presence of mites in cereal-based products leading to the development of asthma and some molds that produce mycotoxins. There is also a safety issue with the presence of pesticides remaining in the harvested part of the crop, when high levels of diseases or pests were present during the growing season and were controlled to protect the quality of the product. Extensive testing to set maximum acceptable levels for both mycotoxins and pesticide residues is in progress. Typically, the agreed limits are based upon levels measured in food that is currently available and that has found to be safe. Whilst food safety is obviously a serious issue, the food crops currently produced are of a very high standard. In many countries it may appear that safety limits are now used as a reason for rejecting a proportion of the crops where production is high, rather than because there is a serious risk to consumers.

Healthy Plants

Once a seed has germinated and developed into a seedling, it will grow to maturity over a period of weeks, months, or years depending upon its genetic makeup and the nutrients available to it. During this time, photosynthesis is carried out within the chloroplasts of the green plant cells. Intercepted solar energy is used to convert carbon dioxide and water into carbohydrates and oxygen. The simple carbohydrates produced in this way are then processed into starch

(for efficient storage), the structural component of cell walls (cellulose), fats, oils, or proteins.

For a plant to be healthy, photosynthesis must be efficient, the required raw materials must be available, the chlorophyll within the leaves must be working correctly, and the carbohydrates produced must be transported to the growing points of the plant. Plants need various mineral nutrients (such as nitrogen, phosphorus, potassium, sulfur, calcium, magnesium, manganese, and molybdenum) for the more complex molecules that they produce during growth. When these nutrients are in short supply, symptoms of deficiency are seen in the plants and damage caused by disease may be increased. The accumulation of carbohydrates is important in maintaining the plant's species when they are sequestered either into the seeds of grain crops, or storage organs as with potatoes. Vegetative propagation via rhizomes or stolons may also give rise to new mature plants in some plant types.

Vulnerable Stages in Plant Growth

The "success" of a pathogen or pest depends upon its ability to invade a host, grow, and reproduce before causing death to the plant. Diseases and pests cause most damage to plants when they act upon critical points in the processes involved in plant maintenance, growth, and reproduction. These can be summarized as follows.

1. Reduction in the rate of plant photosynthesis. The reduction of green leaf area caused by pest damage or diseases such as mildew, scab, and rust will impair the interception of solar radiation.
2. Reduction of the plant's ability to take in water and nutrients by preventing uptake through the roots or blocking the transport through the plant. As the components necessary for photosynthesis are restricted and the supply of water ceases, plants become chlorotic and wilted. Diseases falling into this category include *Fusarium* foot rot, eyespot, and take-all; pests include slugs and insect larvae that damage stem bases and roots.
3. Interference with seed formation leading to infertile flowers, nonviable seed, or the replacement of seed with fungal structures. Damage caused to the lower stem can lead to infertile flower heads that do not produce any seed and may be described as "blind," or if seed is produced it is severely shriveled and of poor quality. Damage caused by insect larvae feeding on developing grains (e.g., wheat orange blossom midge) may prevent normal germination of the seed and will reduce its quality. Seed production is prevented in several species of grain by smut, bunt, or ergot infection.

Plants are more vulnerable to attack at certain points in their life cycle than at others, particularly during the early stages of growth. As their biomass increases, they become more resilient to damage; this is illustrated in cereals with the damage caused by bulb-fly larvae. When the eggs of the bulb-fly hatch, each larva burrows into the base of a plant and feeds on the stem and leaf material there, this prevents the flow of nutrients and water up to the green leaves, resulting in their death. When the eggs hatch early in the season, there will only have been a single tiller produced; with this destroyed, the entire plant will die. When the eggs hatch at a later stage in the season, several tillers will have been produced and even if one or two are killed, the remainder will continue to grow and more tillers will be produced. By the time, the crop has reached maturity, there will be little effect on overall yield.

Another example is aphid infestation of canola (oilseed rape). Because aphids feed via a proboscis that must be pushed into plant tissue before sap can be extracted (Figure 2), they attack new, tender shoots

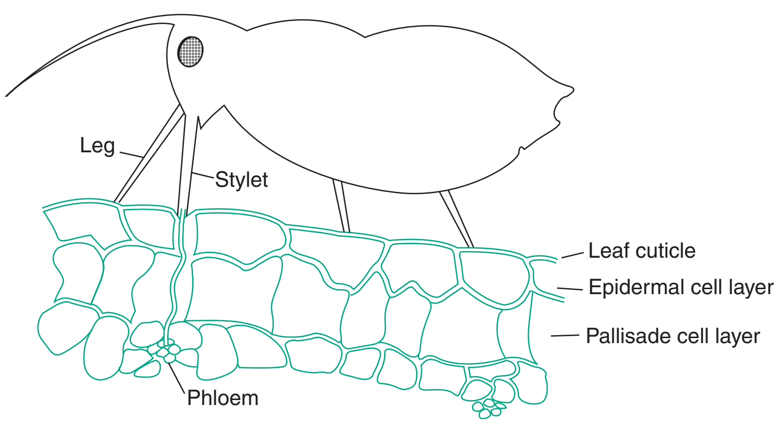

Figure 2 Aphid feeding on plant sap through its stylet.

and are unable to penetrate older stems. A crop at an early stage in development contains plants that are completely accessible to aphids and may be killed if sufficient numbers build up during this vulnerable stage. Once plants have grown and have tougher stems, only their new shoots and flower buds can be penetrated. As flower sites are particularly tender, the fertility and amount of seed set may be reduced or the yield may be adversely affected with the restricted energy reserves available for storage within the seeds.

Storage conditions are very important to keep seeds and tubers healthy and to start with a clean crop the following season. Seedlings are extremely vulnerable to attack from many types of organism and severe attacks at this stage are likely to be fatal. Once seedlings have reached a certain stage, they are equipped better to withstand attack. If the pest or disease is present in epidemic proportions, however, they are still at risk and at best, may suffer reduced yield. With the presence of inoculum and the means for its spread, diseases rapidly take hold. Attacks to flowers tend not to be fatal, as the plant is mature at the stage when they are produced but yield is still likely to be reduced.

Plant Infection by Pathogens

The causal agents of plant diseases (pathogens) may be airborne, soilborne, splash-dispersed, or carried by insect vectors. These causal organisms are mainly fungi, bacteria, or viruses, although very few bacteria are associated with cereal diseases.

Fungal Diseases

A fungus is a multi-celled organism that lacks photosynthetic ability; therefore, it relies on other organisms (animal or vegetable) to provide the necessary energy for growth and reproduction. If a fungus does not cause much damage to its host organism, it is described as saprophytic, but if the host is greatly damaged or killed, the fungus is categorized as parasitic.

The main causal organisms of plant diseases are the true fungi (*Eumycota*); the three subdivisions into which most pathogenic fungi fit are:

1. the *Ascomycotina* (e.g., powdery mildew – *Erysiphe graminis*);
2. the *Basidiomycotina* (e.g., the rust and smut fungi); and
3. the *Deuteromycotina* (e.g., cereal eyespot – *Pseudocercosporella herpotrichoides*).

The first two groups contain fungi that have both asexual (cell division) and sexual (cell fusion then division) stages to their life cycles, the third contains fungi whose sexual stage has not been identified (if they have one). Table 1 shows examples of cereal diseases caused by fungi.

The sexual stage allows the alteration of genetic makeup over time as many generations are passed through. By this process, the fungus may gradually change in a way that enables it to infect plants that were previously resistant to its attack. When this occurs, the resistance of the plant is described as having broken down (although it is actually the pathogen's properties that have changed rather than those of the

Table 1 Examples of cereal diseases caused by fungi

host plant). During the course of several years, a newly developed crop cultivar will initially be resistant to infection from the strains of pathogens present in the environment and a large area will be sown with this cultivar. In this way, a heavy selection pressure is placed on the fungi, as only those that able to overcome the plants' resistance will be able to survive. Any strains of fungi that develop the ability to infect their host plants will have a great advantage and will multiply quickly. As the numbers of this "new" strain increase in proportion to the "old" strains to which the plant cultivar was resistant, the plants are more frequently attacked until the resistance loses its strength completely. This is an important consideration when producing crops, and is one of the key driving forces behind plant breeding programs, in addition to improving yield and crop quality. The process of pathogen evolution and its effect on a monoculture of a cultivar has been described as a cycle of "boom" and "bust" in terms of crop success. As the success of a new resistant cultivar encourages growers to use it, there is a boom, but when the resistance breaks down, there is a bust as the cultivar rapidly succumbs to widespread disease.

Life cycle of brown rust in wheat (*Puccinia recondita*) This fungus may infect wheat and rye, but is particularly damaging to the former host. Disease symptoms occur on the leaf blades in the form of scattered orange-brown spots (uredosori) that are often surrounded by a pale halo of leaf tissue.

Dispersal The uredosori release huge quantities of uredospores to be spread by the wind, particularly in warm weather with frequent rainfall (although hot conditions will halt its spread).

Penetration When a uredospore lands on the surface of a plant under conditions of suitable temperature (15–20°C optimum) and humidity (high), it will produce a germination tubule. As the tubule grows between the plant cells, it is recognizable as hyphae and will penetrate cells producing a haustorium, which it uses to remove nutrients from the host cell, thus enabling its own growth.

Mechanism of injury By removing nutrients from many host cells simultaneously, the growing fungus causes areas of chlorosis around each infection site. The growth of superficial mycelium on the leaves and the localized areas of chlorosis and necrosis reduce the green leaf area available for converting solar radiation into nutrients by photosynthesis.

Propagation Once established at an infection site, the fungus will produce fresh pustules (uredosori) that will release further uredospores. The infection cycle may be repeated many times during the summer growing season. The pathogen is able to survive between seasons by living on volunteer plants and straw in this way. As temperatures fall, teliospores and haploid basidiospores are also produced, which infect a noncereal host, such as meadow rue (*Thalictrum flavum*), and the cycle continues through winter and releases accidiospores that are able to infect cereals again.

Control Resistant cultivars will prevent infection from established fungal strains. Regular monitoring of the crop for early signs of disease will allow fungicide to be applied in time to prevent serious damage from new fungal strains.

Bacterial Diseases

All bacteria are single celled with no cellulose cell wall, chloroplasts, or mitochondria within them; they can only be seen as individuals under a light or electron microscope. Plant pathogenic bacteria have rod-shaped cells and rely on contact with a host organism to obtain the energy they need to grow and reproduce. They do not have a dispersal mechanism, so must rely on naturally occurring vectors (such as rain, insects, and soil-dwelling organisms) to move their cells into contact with a suitable host. Plant cells are well protected by rigid walls and a cuticle, so bacteria are only able to gain entry through wounds or natural openings (e.g., stomata). Diseases caused by bacteria are rare within cereals; they are a greater problem for broad-leaved plants and their fruit or tubers. The types of diseases caused by bacteria can be split into three main groups according to the way in which they act upon the host. Table 2 shows examples of cereal diseases caused by bacteria.

1. Parenchymal diseases are recognized easily once they have taken hold; in the affected area of the host plant, the cell walls are broken down and become incapable of holding their original shape, resulting in a soft, weak mass.

Table 2 Examples of cereal diseases caused by bacteria

Crop(s)	*Disease*	*Pathogen*
Maize	Bacterial wilt	*Erwinia stewartii*
Oats	Halo blight	*Pseudomonas coronofaciens*
Wheat	Yellow slime (Tundu disease)	*Corynebacterium tritici*

2. Vascular diseases cause the host plants to wilt as the xylem and phloem pathways become blocked by thick, sticky substances produced by the bacteria, preventing transport of water around the plant.
3. Meristematic diseases occur when bacteria cause excessive plant growth in a localized area by stimulating either cell division, cell enlargement, or a combination of the two.

Life cycle of bacterial wilt in maize (*Erwinia stewartii*) Symptoms range from mild to severe: long, pale green/yellowish streaks on leaves extending from the points of insect damage; early flowering and the production of very few ears; and no ears produced, or complete plant death.

Dispersal The main vector of these bacteria is the corn flea beetle (*Chaetocnema pulicaria*), but the soil-borne larvae of *Diabrotica longicornis* and *Phorbia cilicrura*, that attack the plant roots, also carry them.

Penetration The vector damages the plant when it feeds, allowing bacterial cells to enter through the wounds and into the host's vascular system.

Mechanism of injury Once inside the host, the bacteria feed on it by producing enzymes to degrade the pectin of cell walls. By-products are produced in the form of sticky polysaccharides that build up to block the vascular system and preventing the normal flow of nutrients around the host.

Propagation Bacterial cells divide rapidly once they have gained sufficient nutrients to enable them to do so. Vectors feeding on infected plants will carry some bacterial cells to other plants and continue the infection cycle.

Control The main method of control is to target the flea beetle (vector) population with early season insecticides; this can be combined with the use of resistant cultivars.

Viral Diseases

An individual virus is submicroscopic (~50 nm across) and can only be seen using an electron microscope; it generally consists of a single strand of DNA or RNA encapsulated within a protein coat. Because of their simplicity, viruses require other cells (e.g., animal, plant, or bacterial) to provide the building blocks and energy required to replicate themselves. Different types of viruses are specifically adapted to infect different organisms; those that infect plants tend to contain RNA and are coated with a simple protein layer when traveling between cells. When a virus comes into contact with a host cell, the RNA passes into the cell, leaving the protein coat on the outside. The RNA causes a template strand (that is complementary to the original) to be formed from the cell's DNA; this template is then used to replicate many strands that are identical to the original. Upon entering the host cell, the initial viral RNA strand causes the host cell to produce enzymes (RNA polymerases) that catalyze the replication of new viral RNA strands. The plant cell is also used to produce the protein coating to enclose the new RNA strands before the cell is completely destroyed and the new batch of viruses released and may remain in the intercellular spaces to infect new cells, or may enter the plants transport system and be dispersed throughout the plant. Table 3 shows examples of diseases caused by viruses.

When they are outside a host's cell, viruses are relatively fragile and easily killed. The success of viruses is due to the way they are actively spread from plant to plant via various vectors such as aphids, leafhoppers or whitefly (all of the order *Homoptera*), soil-dwelling nematodes, fungi, or within seeds. These insect and nematode vectors share a common morphology in their feeding organs; they have a protruding "beak" called a stylet that is able to penetrate the outer cuticle of plant surfaces and enter plant cells. Within this group of vectors, the two main categories into which virus transfer falls are termed "stylet-borne" and "persistent."

Stylet borne As the name suggests, viruses transmitted in this way are carried from an infected plant by a vector within or stuck on the outside of the stylet

Table 3 Examples of cereal diseases caused by viruses

Disease	*Vector*
Barley stripe mosaic virus	Pollen/infected seed
Barley yellow dwarf virus (BYDV)	Aphids especially *Rhopalosiphum* spp.
Barley yellow mosaic virus	*P. graminis* (soil fungus)
Maize chlorotic dwarf virus	*Graminella nigrifrons* (leaf hopper)
Maize dwarf mosaic virus (MDMV)	Many aphid species
Maize mosaic virus	*Peregrinus maidis* (plant hopper)
Maize rough dwarf virus	*Laodelpax striatellus* (plant hopper)
Oat blue virus	*Macrosteles fascifrons* (leaf hopper)
Oat mosaic virus	*P. graminis* (soil fungus)
Rice dwarf virus	*Nephotettix cincticeps* (leaf hopper)
Rice tungro virus	*N. impicticeps* (leaf hopper)

after a feeding session from the outer layers of a host plant. When a new feeding place is reached (on another plant or a different location of the same plant), the plant's cuticle is punctured and the viruses delivered from the stylet into close contact with internal plant cells. The "soybean mosaic virus" is transmitted in this way.

Persistent This type of transmission occurs by the movement of infected sap taken from the host plant's transport system. When the vector feeds on the sap of a plant containing virus particles, it ingests the mixture without harming the pathogens' structure. The virus particles may remain dormant within the vector for several hours allowing a greater chance of spreading the disease to a new plant, or they may retain their virulence and be able to cause infection immediately as they come into contact with a host cell. Upon moving to a new feeding position, the viruses are injected deep into the transport system of the new plant, as with the "pea enation mosaic virus."

Regardless of the manner in which a virus enters its host plant, once inside it is able to penetrate the host cells, rapidly multiply, and spread causing disruption of normal growth. By repressing production of the plant's necessary enzymes, symptoms are seen on the outside of the plant. These symptoms are the basis for the classification of the different types of virus pathogen:

1. Stunting and dwarfing result from a loss of ability to grow normally.
2. Color change occurs when chlorophyll production is reduced, forming a mosaic, mottled pattern of yellow and green on the leaves. Variations on chlorosis, followed by necrosis, may cause interveinal discoloration or concentric rings of yellow and brown.
3. Leaf and stem distortion results from abnormal cell proliferation or development as occurs in virus leaf curl diseases.

Life cycle of barley yellow dwarf virus in cereals Despite its name, barley yellow dwarf virus (BYDV) infects many grass species, including barley, oats, wheat, and rye. Symptoms are seen as bright yellowing (wheat and barley) or reddening (oats) of the leaves from the tip back towards the stem. Other symptoms may include necrotic spotting, stunting, increased tillering, and bleached, sterile ears.

Dispersal Many species of aphid carry this virus from one feeding site to the next. After an aphid feeds for 24–48 h on an infected plant, there is a short latent period (during which the virus will not be passed on), then the virus will be transmitted from that aphid for the next few weeks.

Penetration The virus particles are injected by the vector directly into the host's vascular system from which they are able to enter large numbers of host cells throughout the plant with relative ease.

Propagation and mechanism of injury As the viruses replicate themselves, they use the host cell contents and leave empty, dysfunctional cells behind them. Due to their rapid multiplication, they cause large areas of cells to become necrotic simultaneously. When a crop is infected at the seedling stage, large areas can be wiped out completely, as the plants grow, they are able to tolerate the infection better, if they are not infected until late in the season, there will be very little damage to the crop.

Control The only effective method is by reducing the aphid (vector) population, this can be combined with the use of resistant cultivars and reducing the amount of wild grasses surrounding the crop as these are a source of inoculum.

Plant Damage by Pests

Birds and Mammals

Although some species of birds will eat insects rather than seed, there are those (sparrows and pigeons in particular) that will eat seeds at every opportunity: during storage, when planted in the field, at germination and during early plant development. If seeds are damaged, they are unlikely to remain viable and will not germinate. Wild burrowing and grazing animals such as rabbits, hares, gophers, badgers, rats, and mice (and their relatives around the world) can be serious pests once seeds have germinated. If a germinated seed is damaged, the seedling produced may be stunted or grow abnormally if at all. If young plants that are attacked survive, they are likely to produce a weak plant with a reduced capacity for reproduction (i.e., lower yield). Once plants are well established, they are less likely to be killed by an attack, particularly in the case of monocotyledonous cereal plants where the growing point is at or below ground level; continuous grazing can be tolerated until stem elongation begins in earnest. Dicotyledonous *Brassica* sp. can also survive being pecked at by pigeons, provided they are not completely mown down to the ground; they have multiple growing points and will compensate by sending out new growth from the leaf axils.

Insects

Although it may be stating the obvious, insects have smaller mouths and so prefer more tender parts of plants than larger pests. They cause particular problems for younger plants; the smaller the area of green leaf to begin with, the less damage it takes to destroy it. Insects are either designed for grazing leaves (with jaws) or for piercing leaves then sucking out the sap (with a stylet). Many insects are attracted to flowering canola (oilseed rape) and similar crops in the field where they lay eggs. Once these have hatched, the insect larvae devour the leaves and flowers as they grow. Other insect pests pose a problem in stored grain, particularly weevils, beetles, moths and their larvae.

Nematodes and Molluscs

In addition to the aerial plant parts, slugs, nematodes, and some insect larvae attack the roots. Of the pest nematodes, some feed on the internal and some on the external parts of plant roots using a stylet in a similar way to aphids.

Disease and Pest Management

"Control" of pathogens and pests does not tend to be absolute, therefore, "management" seems a more accurate description, and especially when there is a greater emphasis on integrated management. With regular monitoring and careful forward planning, an integrated approach to disease management can be taken to protect the quantity, quality, and safety of the yield. Management of diseases and pests is essentially the prevention of disease and pest epidemics, as the causal organisms are always around somewhere, but must be prevented from building to damaging levels. The disease triangle summarizes the three main factors involved: environment, host, and pathogen (or pest), one at each point of the triangle. If these three elements remain in balance, an epidemic is prevented, if the pathogen/pest becomes too strong, the host becomes vulnerable or the environment favors the pathogen/pest, then an epidemic is likely and control measures must be taken.

Husbandry

Physical methods for disease and pest management include the following:

- Soil preparation such as plowing to expose insects to their predators (birds) and to bury the remains of the previous season's crop, which may harbor overwintering stages of pathogens or the eggs of insect pests.
- Informed choice of crop variety to match environmental conditions in which it is to be grown; the variety should be suitable for the soil type and general weather conditions in a given location, with proven resistance to endemic pests and diseases that cannot be effectively controlled by other means.
- The use of crop rotations to prevent a buildup of problem diseases or pests due to providing a continuous succession of host plants.
- Elimination of alternate and alternative (weed) hosts of crop diseases and pests where possible.
- Timing sowing to allow plants to become strong enough prior to insect or disease attack or to delay germination until the threat has receded.
- Encouraging rapid germination and early growth to build up strength quickly and enable prevention of severe damage resulting from initially mild infestation.
- Understanding the life cycles of diseases and pests to be able to manage them, using the results from modeling studies to enable forecasting of likely onset of epidemics.
- Reduction in size of areas in which a single cultivar of a single crop is grown, for example, reduces the pressure on the pathogens to overcome plant resistance.
- Following the rules for notifiable diseases, in order to prevent them from spreading.

Resistance

As plants are literally rooted to the spot they grow in, they are not able to escape pests and diseases. They are, however, able to put up some defenses to the attacks that come their way. In addition to the basic structure of plants (i.e., the location of their growing points), integral properties such as thorns, thick cuticles, or chemical composition act as a deterrent, a blockade, or even a toxin to the right invading organism. Other attributes may only become activated once the plant is threatened, e.g., lignification of cell walls surrounding an area being invaded by a pathogen. In the case of genetic resistance to pathogens, resistant plants are able to deny the invader the nutrients or chemical components they require to grow or reproduce. When resistance breaks down, the pathogen has altered to allow it to overcome this.

Genetic resistance may be due to the presence of a single major gene, which confers protection against a matching virulence gene within the pathogen (gene-for-gene concept). If a pathogen containing an altered virulence gene tries to infect the host, it is likely to succeed, as the resistance is specific to the initial type of virulence, not this new one. This can be observed at

the seedling stage when new varieties are being screened for their usefulness. This type of resistance is most useful when (1) a new disease problem arises, (2) disease spread is slow, and (3) a single type of pathogen (a single virulence gene) becomes stable within the pathogen population.

Polygenic resistance involves the presence of several resistance genes within a single host cultivar, this confers protection from a range of virulence genes. It is not fully exhibited until the plants mature, so is screened for in the field by looking for a reduced rate of pathogen sporulation.

Biotechnology has allowed improved direction to be used when breeding new crop varieties. In particular, it has been possible to introduce genes that code for Bt proteins into transgenic lines of maize and cotton to confer protection against various insect pests and to remove the need for spraying with insecticides. These crops are widely grown in northern America and have proven themselves to be very effective.

Chemical Control

The use of pesticides to kill diseases and pests has been exploited in the past in order to meet the market demands for clean, healthy produce. These can be used to accurately target pest organisms by their methods of application: seed dressing, granules, and liquid sprays applied to leaves or soil as appropriate. Contact pesticides cause the death of the pathogen or pest either by direct treatment with spray, dust or vapor or when the pathogen or pest touches the chemical residue on leaves or in soil. In the case of pests, a stomach poison may be used that is only effective when ingested either from the external surface of foliage, within the sap of a plant or when used as a bait. The different types of chemical may be short-lived and require immediate, direct contact with the pathogen or pest, or may be longer-lasting; entering the system of the host plant and remaining there for some time before acting on the attacking organism. The chemical formulation of pesticides appears to be designed to work in more than one way (i.e., on contact and systemically) in order to retain its efficacy over as long a period of time as possible. The overall aim of all pesticides is the same; to prevent the pathogen or pest from growing or multiplying. This is achieved by disrupting the normal function of the invading organism, thus protecting the host plant and allowing it to grow and reproduce.

The development of new, effective pesticides is a long process. An initial product development stage is carried out in controlled environments until suitable formulations are produced. Once the safety of the compound is understood sufficiently, it is tested for efficacy and crop safety by extensive field-testing before approval for use is given. The high cost of development and testing is transferred to the end product, making the use of chemical crop control difficult to justify in some cases.

Integrated Pest Management

As the agricultural industry has become unable to justify the cost (both monetary and ecological) of using chemical control methods alone, a greater emphasis has been put on integrated pest management. By understanding the epidemiology of the organisms causing the damage, it has been possible to reduce the amount of chemical required for pest control. The strategic use of chemical control when it will be most effective and only when it is absolutely necessary has led to this reduction. Instead of treating a crop when evidence of disease or pests is first observed, conditions are optimized for plant growth and reduced for pathogen and pests. Optimization of crop husbandry to maintain strong plants throughout the season plays a vital role, but the effect that any chemicals may have on naturally occurring beneficial insects or predators must also be taken into consideration.

Whole Plant Utilization

L Munck, Royal Veterinary and Agricultural University, Rolighedsvej, Frederiksberg C, Denmark

Introduction

In subsistence plant husbandry, all parts of the crops were needed for survival and were, therefore, carefully utilized for food and nonfood purposes. Introduction of the monetary economy ended the isolation of the agricultural village. It was integrated into a national and later an international economy, leading to increased competition and specialization.

New technology based on exploitation of the nonrenewable fossil fuels supported this change at an ever-accelerating pace. The local biological and agricultural production chains, which to a great extent were self-sufficient, yet low-producing, were broken up due to new technology, transport, and trade. To cite an example, with the changed production system, the straw, which was left by the new efficient combines as waste in the field, was burnt after grains were harvested. The dramatic change from a local to a more global economy increased production and created competition for each individual class of products. It brought about a specialization, economically favoring farmers who had a local production advantage for a given specific product. Specific monocultures were, thus, regionally favored. At the same time, a range of traditional, agricultural nonfood products were phased out by substitutes produced and supported by gas, oil, and coal.

Since the oil crisis in the 1970s, there has been an increased awareness of the importance of system research and ecological sustainability in the agro-industrial production chains and in the derived agro-industry. Research programs were introduced by governments and international organizations to study renewable production systems that take care of the whole plant in a balanced utilization for food, feed, and nonfood purposes. How would it be possible to utilize modern technology to re-establish, in a new way, the biological production chains in a recycling effort to conserve fossil energy and avoid an increase of carbon dioxide in the atmosphere, which may contribute to a climatic change? What governmental incentives were necessary for such a change to be driven by the monetary system and by the market?

Value-Added Fractionation of Whole Grain Crops

The coarse botanical components of the cereal plant can be divided into the internode (stem or stalk), nodes (divisions between internodes at the insert position of leaves), leaves, husks (or cobs from maize), and seeds. Straw is defined as the remains (leaves, internodes, and nodes) that are left in the field after combining. Internodes may contain marrow, which is especially well developed in maize and sorghum. Internodes, nodes, leaves, husks, and cobs are lignocellulose products. These contain large amounts of cellulose and hemicellulose bound to lignin with protein as a minor component.

Each overground grain crop is, in essence, botanically and chemically inhomogeneous and may be fractionated into a range of different components. Thus, straw can be coarsely milled in a simple disk mill to produce flour from leaves, marrow, and chips from internodes and nodes which are separated by a sifting machine yielding fractions with entirely different chemical and physical properties (see Figure 1).

Unfractionated straw has a mediocre value for feed as well as for paper. However, the leaf fraction has improved protein and energy value for feed, and the

Figure 1 Dried stem of maize separated by disk milling and sieving into a meal fraction from the marrow and into different sizes of chips from the cell walls of internodes and nodes.

internode part has as high a content of α-cellulose, as wood used for paper. There should, therefore, be an economic incentive for a value-added fractionation of straw, tailored to different uses. The total amount of the world production of cereal grains amounts to over 2 billion tons (Gt) of grains and at least a similar tonnage of straw, which implies ~1.1 Gt of internode chips and 0.9 Gt of leaf and marrow meal.

The Botanical, Chemical Composition, and Productivity of Grain Crops

Plant-breeding efforts have increased cereal seed yield more than the whole crop output, because new varieties have been bred for increased grain-to-straw ratio, changing the proportions of the whole plant produce by favoring seeds.

In Table 1, indicative Danish data regarding yield and composition of whole crops from barley, wheat, rye, oats, and maize show a variation between extreme samples in grain-to-straw w/w index from 0.52 in barley to 1.74 in maize. The average values indicate that short straw breeding, to favor grain yield under Danish conditions, has apparently been most successful in barley, followed by wheat, maize, rye, and oats. Winter wheat and maize, despite the fact that the latter crop is not fully adapted to the Danish climate, produced most grain (top yield 9.1 and 6.9 $t\,ha^{-1}$, respectively) and straw (top yield 8.5 and 10.6 $t\,ha^{-1}$, respectively). The straw from each sample of the cereal material in Table 1 was hand-dissected into internode, leaf, and node and the fractions were weighed and analyzed (see results in Table 2). The internode is, on an average, the largest component of straw, ranging from 68.7% in rye to 40.4% in maize. The leaf portion ranges from 48.4% in barley to 20.7% in rye, while the node fraction is relatively high in maize (max. 16.6%) and low in barley (min. 1.0%). It is also seen in Table 2 that α-cellulose is generally higher in the internode (42.2–38.3%) than in the leaf (30.3–28.2%). The leaf fraction has the highest protein content of 3.5–8.3% compared to 2.0–3.7% for internodes. The leaf fraction shows constantly higher values with respect to ash and silicon than internodes. Ash and silicon content depend to a great extent on the soil conditions, with high content in loamy soils compared to sandy. The silicon in the internode fraction in several samples

grown in sandy soils is below 0.1%, which is a great advantage in the manufacture of chemical paper pulp and paper. *In vivo* and *in vitro* digestibility trials give ~20–30% higher values with cereal leaf compared to internode (e.g., barley *in vivo* 51.3% versus 41.0%). Leaf meal energy value for fuel varies from 16.8 MJ per kg d.m. in barley to 17.0 MJ per kg d.m. in barley straw pellets compared to 18.4 MJ per kg d.m. in wood.

Products from Whole Plant Fractions

Today, most of the whole plant products are utilized for food and feed. The consumption of grains and grain products for the nonfood sector is relatively small compared to that of food and feed, although in absolute terms, millions of tons of starch, oil, and lignocelluloses are consumed globally by the industry for nonfood purposes.

Research on agricultural, nonfood substitutes for import was high during the Second World War, especially in the USA within the USDA. After the energy crisis in the 1970–80s, research on developing renewable resources for products and energy was again initiated in countries such as USA, Holland, England, and in the Scandinavian countries, as well as in the present European Union. Perhaps the most important driving force was the steadily increasing surplus in cereal production in industrialized countries at the end of the twentieth century. There was, thus, a clear governmental interest in nonfood cereal products that could eliminate the surplus, while providing income to farmers.

Starch, cellulose, and oil are the major chemical components of industrial interest. Figure 2 gives the whole plant utilization potential of maize as an example. Very large scale industrial units for maize grain utilization is a significant component. These units feature dry and wet (starch) milling of maize, where oil (from germ) and gluten protein (for feed) come as coproducts from starch manufacturing. There is a wealth of possibilities for utilizing the starch polymer after modification by means of organic chemistry or microbiological transformation to, for example, plastic molds, ethanol, acetone, and butanol. Starch from maize, wheat, and potatoes is consumed in large amounts by the paper industry. Here, starch derivatization with ionizing chemicals is used in the form of cation and anion starches as additives to increase paper strength as well as for coating. Graft polymers with vinyl and acrylic monomers can be produced from granular and gelatinized starch for production of plastic films, molded products, etc. Such a solid polymer of starch with acrylonitril can absorb many hundred times its weight in water without being dissolved. These “superslurpers” could be used for applications in hygienic products and medical care, as well as in agriculture for coating seeds and to conserve water under arid conditions. Starch xanthates can be used as carriers for encapsulation of seeds with pesticides.

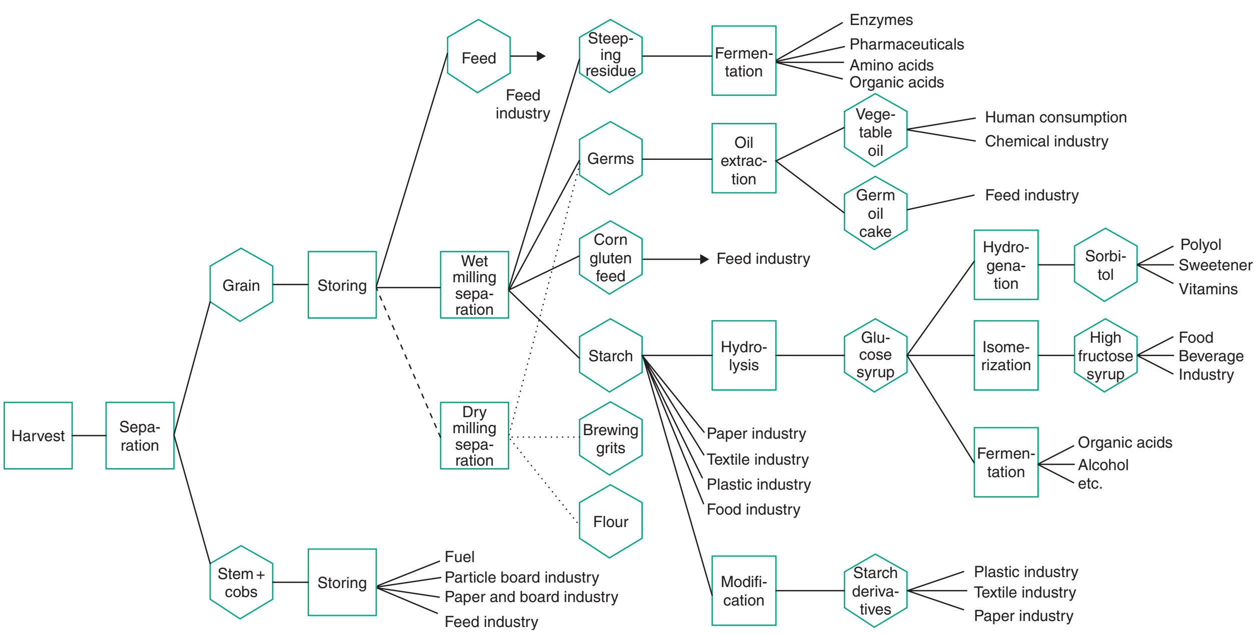

Figure 2 Whole plant utilization with maize as an example. (Munck L (1993) On the utilization of the renewable plant resources. In: Hayware MD, Bosemark NO, and Romagosa I (eds.) *Plant Breeding. Principles and Prospects*, pp. 500–522. London: Chapman and Hall.)

The lignocellulosic fractionation options demonstrated in Table 2 regarding stem and leaves are sparsely utilized today. The current world production of paper pulp is in the order of 150 million tons (Mt), of which 12 Mt comes from cereals and grasses corresponding to ~30 Mt of whole straw. Existing fractionation and treatment technology can exploit the lignocellulosic resources of cereals much more effectively than is the case today. Most of the straw produced today is either burnt in the open or collected and used as bedding material for animals and as low-quality feed. Straw can be pelleted into a high-grade fuel. It can be instantly treated with alkali and steamed in a pellet press to loosen the lignin bonds, which greatly improves the physiological energy utilization of feed for ruminants. The same alkali-treated pellet can be used as semi-manufactured material for paper pulp. Short hardwood fibers from birch, etc., and internode fibers are similar in length, but the latter are much more slender. The smaller diameter of the straw fiber seems to have no adverse effect on the technological properties of the paper derived from it. The fiber length from lignocelluloses in the leaf fraction is shorter than that from the internode fraction. The latter is preferable for paper-pulp processing because of its high content of α-cellulose and low level of silicon. Silicon may be a problem when straw is used as raw material in the paper-pulp industry, because it prevents recycling of the alkali – black liquor – due to gelling and insulation of the cooker.

The use of straw fractions for particle boards is an overlooked application today. The internode fraction from, for example, wheat, rye, maize, and sorghum straw compressed with synthetic glues yields a product strength as high as that of particle boards from wood chips. The texture of this type of boards can be varied by using different size fractions from internodes, making an appealing natural product. Starch can substitute formaldehyde in phenolic polymers, which can be used as binders in particle boards. Bran from phenol-rich sorghum varieties can also be used for glue making. Another more elegant solution for glue is enzyme treatment of the lignocellulose matrix of the internode material. This enables the use of the natural component lignin as a binder by introducing free radicals before pressing.

Most of the vegetable oils from grains (e.g., rape, sunflower, and maize) are used in the food sector. There is, however, a significant nonfood market for these vegetable oils in soaps and detergents, paint and varnish (emulsifiers and drying oils), lubricants, greases, cosmetics, and pharmaceuticals. Rapeseed oil for driving diesel engines in, for example, tractors and buses is at present used in the public sector in Europe in an effort to reduce pollution and improve carbon dioxide recycling. This is more effective per unit of biomass, compared to using ethanol for fuel obtained microbiologically from hydrolyzed starch or lignocellulose, because the fermentation process involves liberation of large amounts of carbon dioxide.

Whole Plant Utilization Production Systems – Integrated Plant Conversion in Biorefineries

It may be concluded that there are great opportunities in utilizing whole plants in a variety of food, feed, and nonfood applications. A major obstacle is, however, local organization of the necessary links between decentralized agriculture and centralized industry, for a flexible whole plant utilization of a range of different crops, simultaneously, in accordance with signals from the market. The local cultural role of farms and farmers in society based on traditions has prevented the integration of the local production of vegetative materials and the processing industry. Sucn an integration has, however, taken place in the forestry industry. Oil palm plantations and the cane and beet sugar industries are examples of industries that are closely connected to the agricultural production. They exercise within a defined crop a whole plant utilization strategy. Since the 1960s, the idea of local agricultural preprocessing stations or biorefineries as a necessary link between agriculture and industry began to emerge in countries such as Denmark, Sweden, Holland, and the United States.

In the following section, the Danish research applicable for northern European conditions is cited as an example. In the 1960s, machine stations and cooperatives for manufacturing of lucerne and grass pellets by high-temperature, oil-heated drum dryers demonstrated the needs and possibilities in changing the structure of local agriculture. Grass and lucerne was harvested as a whole crop by self-propelling choppers (Figure 3a) several times during the growing season. These were then brought in containers (Figure 3b) to the drying station where they were dried and pelleted for sale to the feed industry. A number of very wet harvesting seasons in the 1960s stimulated the use of the whole crop harvesting strategy for other crops such as barley, wheat, broad beans, and maize. The whole biomass was dried in the drum dryer and afterwards separated into seeds and straw. The straw could then be treated in the pellet press of the drying station by steam, sodium hydroxide, and urea to produce high-quality feed for ruminants. In Denmark, in the 1960–70s, a major oil company subsidiary ran this type of biorefinery in a limited sense in Jutland, where whole crop

(b)

Figure 3 The principle of whole plant harvesting exemplified by barley: (a) self-propelling harvesting chopper loading the coarsely chopped plants into a container; (b) when the container is full, it is transported by truck to the biorefinery for separation of the crop components and further processing.

harvesting of lucerne, grass, and cereals from farmers in the area was integrated with a large milking cow unit.

On the island of Bornholm, a demonstration and research biorefinery unit, financed by EU-projects, has been in operation since 1988. It is located adjacent to a feed factory with a drum dryer and a chipboard factory for wood chips. Large-scale trials were performed with fractionation of wheat and rape straw into internodes and leaf meal. High-quality chipboards were produced from internodes chips.

In cooperation with chemical and paper industries, an EU "Cascade" production chain project was implemented, whereby a cation starch product was developed from bran-separated wheat flour in an environmentally closed dry process. The performance of this resource-saving product in paper production was fully comparable to that of cationic wheat starch. The quality factors for performance were monitored throughout the production chain with near infrared spectroscopy (NIR) interpreted by chemometric (multivariate) data analysis. On the basis of the NIR analysis, the quality of wheat optimized for the whole process could be defined and predicted, at the raw material stage. Today, the modified wheat flour product is produced and sold in Germany in competition with modified starch.

Extraction of oil from, for example, rapeseeds normally involves extraction with explosive hydrocarbons in very large factories. A process suitable for local, smaller-scale production was developed by which the rapeseeds were milled and blended in water. Enzyme treatment opened up the oil-filled cells and the oil was extracted from the emulsion by a centrifuge, just as cream and butter are extracted from milk. A high-quality food protein fraction was obtained as a coproduct.

After the oil crisis in 1973, Denmark's lucerne- and grass-drying and pelleting industry, one of the largest in the world at that time, vanished due to high oil prices. Some companies survived by switching to coal. In drying cereals as a whole crop, the pelleted leaf fraction is enough for sustaining the drying process. The implementation of this possibility is dependent on the price of straw. The Danish experience, applicable to the wet and tempered production and harvesting conditions in northern Europe, is contained in the biorefinery concept demonstrated in Figure 4, comprising a machine station, a drum dryer, crop fractionation equipment, and a feed factory serving a few thousand hectares. Compared to the present farm system with individually run units of $\sim 50-100$ ha, the biorefinery organization would imply the following advantages:

1. The economic success of the biorefinery should not be judged on the basis of individual products, but on the integrated total output from a flexible diversified production.
2. Because of whole overground plant harvesting (Figures 3a and 3b) and its dryer, the biorefinery organization is independent of harvesting weather. Therefore, a wider selection of whole crops can be safely harvested, separated, and processed as semimanufactured products, ensuring a high quality.
3. The diminished monoculture will lead to improved fertility and less costs for pest control.
4. The field is cleared in one step and a higher yield of both grain and straw is achieved.
5. Harvesting machines and biorefinery equipment will be able to be used most of the whole year, which will improve economy. It will, thus, be able to support a permanent staff, thereby creating local working opportunities.
6. The system can be run by locally produced bioenergy.
7. Transport costs will be minimized. Locally produced high-quality feed pellets from straw and grass will stay in the area, while surplus grains and internode fractions are sent to larger centralized industries outside the area producing, for

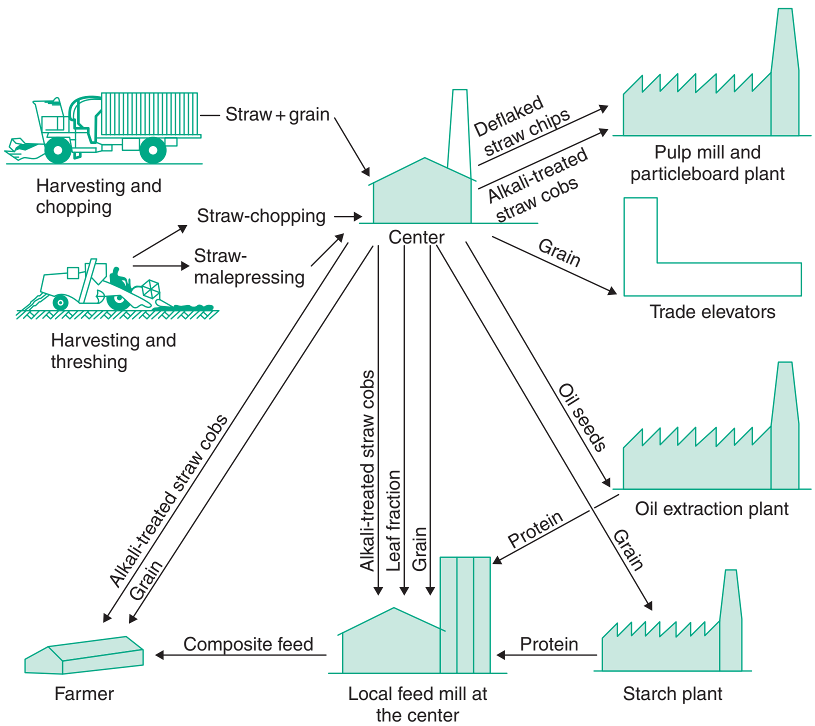

Figure 4 The biorefinery concept as a link between agriculture and industry for implementing whole plant utilization technology. (Reproduced with permission from Bjørn Petersen P and Munck L (1993) Whole crop utilization of barley including new potential uses. example, wheat flour, starch, and vegetable oil, chipboards, and paper pulp.

8. The benefits of the biorefinery principle could only be fully utilized in a network of biorefineries and cooperating industries, which would stimulate sustainable crop utilization and recycling of waste. Local animal and human manure could be collected and used in biogas units, as is done in a few communities in Denmark today. These units could be integrated with the biorefinery. The processed manure products could be recycled to the local agricultural land or sold and exchanged as a hygienic dry product. Thus, the land fertility problem potentially caused by removing too much organic matter (e.g., from straw) from the fields could be solved by re-establishing the biological production chain through recycling the manure.

The whole plant utilization technology included in the biorefinery concept focuses on using agriculture as a vehicle for the development of a differentiated agro-industrial production pattern for food, feed, and non-food products, optimizing the use of local natural resources in closed biological production chains. The principle can be adapted to widely different cases in industrial as well as developing countries, taking local conditions into account.

Economy

The cost-effective use of biological material for non-food purposes in the present economy should now benefit from the fact that the price for cereals (e.g., maize) versus oil w/w has decreased sixfold since 1973. The world market price of pure starch is not far from that of crude oil. Synthetic low-density polyethylene from fossil fuels as well as paper pulp (lignocellulose) is in the order of 2–3 times more expensive than starch. The high price of paper pulp today reflects the high energy and machine costs in the forestry industry. There should be considerable energy savings, compared to the forestry industry, by using existing machinery in agriculture to take care of the internode fraction from plants for paper pulp and chipboards.

It should be advantageous for farmers in countries with existing straw-based paper pulp factories to sell the internode fraction to these industries, while retaining the leaf fraction as feed. Agricultural lignocelluloses for paper and chipboards should be a valuable

produce in many developing countries with vanishing forestry resources. Even if several of the previously discussed plant applications are shown to be profitable today, there are economical, structural, and psychological constraints on a system change from fossil products to renewable plant resources.

To stimulate the nonfood option in agriculture oil, prices should increase from the current US$25 per barrel to reach over US$50 and be kept at this level for a long time. The world now consumes in the order of 50 million gigawatt hours (GWh) of crude oil annually compared to a global production of cereal starch in grains of ~6 million GWh. The plant utilization option is, thus, not of a magnitude that can match our present utilization of fossil fuels, for example, for driving combustion engines, but should, of course, be reserved mainly for food uses. However, whole plant utilization in many specific applications could locally complement food (and animal feed) production without competing with food production. Nonfood technology such as the utilization of agricultural lignocelluloses could be a vehicle for development of local industries by providing employment and thus creating the necessary purchasing power for food.

Research for Implementation of Whole Plant Utilization Technology – How Can Markets Recognize the Long-Range Advantages?

Biological systems are characterized by complex, dynamic, synergistic patterns of interrelations between their components and with the environment. Whole plant utilization technology and the biorefinery are concepts in which biological principles, human needs, and environmental limitations are aimed at being organized, thereby approaching a higher level of production organization and greater benefits than at present. In the development of industries in the 1970s, horizontal integration through diversification was favored, while in the year 2004, the opposite paradigm prevails, maximizing profit by focusing on a core product tailored to specific markets. Accordingly, science today is focused primarily on revealing the partite elements of nature and then putting them together by experimental design in the laboratory, rather than exploring them first in nature by specially devised screening methods. It seems as if systemic concepts like whole plant utilization technology are too complex to be recognized by the present strategies for science, economy, and markets, which largely suppress the synergistic element in an attempt at problem reduction. There are at present new promising parallel developments in the natural, social, and economical sciences, which aim at extending the cognitive limits of human individuals and organizations. This would enable recognition of complex problems in large datasets as patterns on a graphic display by means of new information technology. Grain science is in the forefront here, introducing computerized sensor technology in quality management such as NIR to provide a holistic fingerprint of the physics and chemistry of a sample visualized by multivariate data analytical programs. From huge datasets, specific information may be deduced by comparing samples and by calibration to classic analyses using chemometrics. With such screening methods, it is now feasible to make overviews through large-scale inventories of plant production systems in the field to connect and to tune them to processing chains. For development of whole plant utilization systems, real exploratory data from field inventories and process chains is a must in order to fully understand synergy effects in developing new products and markets from plant raw materials in a sustainable perspective. Thus, biological and electronic circuits can be connected to human selectors, thereby coordinating production, information, and market incentives in a new, more harmonious, and advanced postindustrial production and culture.

PROTEIN CHEMISTRY OF DICOTYLEDONOUS GRAINS

P R Shewry, Rothamsted Research Station, West Common, Harpenden, UK

Introduction

The protein contents of dicotyledonous grain crops vary widely, from less than 20% of the dry weight in the pseudocereals to ~50% in some lines of soybean (Table 1). Extraction and separation of "total" protein fractions shows that all comprise highly complex mixtures, with many components being present in small amounts. However, in all cases a small number of components are present in substantial amounts: these correspond to the seed storage proteins and usually account for half or more of the total seed proteins.

Although specialized storage protein types occur in some species, e.g., lectins in some legume seeds, most of the storage proteins present in dicotyledonous seeds fall into three groups which are defined on their solubility and $S_{20,w}$ values (sedimentation coefficients determined by sedimentation equilibrium ultracentrifugation), which are a measure of their molecular masses. The characteristics of these three types of proteins are discussed, followed by brief descriptions of the storage proteins present in the major dicotyledonous species covered in this encyclopedia.

Table 1 Protein contents and types of storage proteins in major legume, oilseed, and pseudocereal crops

Species	*Protein content (% DW)*[a]	*Storage proteins*
Legumes		
Soybean	30–40	12S glycinin, 7S β-conglycinin, 2S albumin
Pea	25	12S legumin, 7S vicilin/convicilin 2S PA1
Peanut	16–36	13S arachin, 8S conarachin, 2S albumin
Lupin	26–42	11–12S conglutin α, 7S conglutin β, 2S conglutin δ
Oilseeds		
Oilseed rape/canola	36–44	12S cruciferin, 2S napin
Linseed/linola	20–24	12S globulin
Sunflower	15–20	12S helianthinin, 2S albumin
Safflower	15	12S carmin, 2S albumin
Cottonseed	16–22	11S globulin, 7S globulin, 2S albumin
Pseudocereals		
Quinoa	15	11S chenopodin, 2S albumin
Amaranth	13–18	13S amaranthin, 8S conamaranthin, 2S albumin
Buckwheat	13.5	11S globulin, 8S globulin, 2S albumin

[a] % Dry weight.
The $S_{20,w}$ values listed are only approximate with a range of values having been reported for some components.

Types of Storage Protein

Globulins

Globulins are defined as proteins that are soluble in dilute salt solutions, usually taken as 0.5–1.0 M NaCl. Storage globulins with $S_{20,w}$ values of ~7 and 11 are widely distributed in dicotyledonous plants. However, they have been most widely studied from legume seeds. Hence, 7S globulins are sometimes called vicilins after the Viciae tribe of legumes, and 11S globulins, legumins after the family Leguminosae. The individual types of 7S and 11S globulins in different crops are also often given specific trivial names, as listed in Table 1.

It has long been recognized that members of these two protein groups also vary in their precise $S_{20,w}$ values, with legumin-like globulins often having values of 12 or more (e.g., the 13S lupin globulin) and vicilin-like globulins ~8 (e.g., in peanut). Furthermore, not all 11S globulins are readily soluble in dilute saline, with notable exceptions being 11S storage globulins of cereals, which are either insoluble in saline (rice) or only soluble at higher concentrations (0.8–1.0 M) of NaCl (oats). Consequently, the term 11S is used in this article to describe storage proteins with a legumin-like structure and the term 7S to describe vicilin-like proteins.

7S globulins 7S globulins typically have molecular masses of ~150–200 kDa, and have a trimeric structure comprising three nonidentical subunits of mass ~50–70 kDa. The subunits contain no cysteine residues, and hence do not form disulfide bonds, and noncovalent forces stabilize the trimeric proteins. However, this simple structure may be modified after protein synthesis in two ways. First, glycosylation (addition of oligosaccharides) may occur on one or two asparagine residues in one or more subunits of the trimer. This results in an increase in mass of the subunits and lower mobility when separated by sodium dodecylsulfate polyacrylamide gel electrophoresis (SDS-PAGE) with partial glycosylation resulting in additional heterogeneity.

Second, in some species (e.g., pea and field bean), some, but not all, 7S globulin subunits are proteolytically processed at one or two sites, giving rise to polypeptide chains ranging in mass from processed products of ~12 kDa in pea and 18 kDa in bean to unprocessed subunits of ~50 kDa. The processed products remain associated in the trimeric complexes until released by denaturation. The role of this proteolytic processing is not known and it does not occur in some species such as soybean and common or navy bean (*Phaseolus vulgaris*). Although typically trimeric in structure, the 7S globulins may undergo reversible aggregation into hexamers depending on ionic strength.

11S globulins 11S globulins typically have masses of ~300–400 kDa and are hexamers of six nonidentical subunits. Each subunit is synthesized as a precursor protein which is proteolytically processed to release acidic (also called A or α) and basic (B or β) polypeptide chains which correspond to the N-terminal and C-terminal parts of the precursor protein, respectively. The masses of the acidic chains vary in the range of 20–60 kDa but are typically ~40 kDa, while the basic chains usually have masses of ~20 kDa. Thus, a typical 11S globulin comprises six subunits of mass ~60 kDa, each consisting of 40 kDa and 20 kDa polypeptide chains. The basic and acid chains are covalently linked by a single disulfide bond formed in the precursor protein. Whereas the 7S globulins are rapidly assembled into their mature trimeric structure, the 11S globulin precursors are not immediately assembled into their mature hexameric structure but into an intermediate trimer with the hexamer forming only after proteolytic processing occurs to release the basic and acidic chains.

The polypeptide (i.e., subunit and chain) masses of the 7S and 11S globulins discussed below are summarized in Table 2.

Structures of 7S and 11S globulins Simple comparisons of the amino acid sequences of 7S and 11S globulins show little or no evidence of homology, but

Table 2 Polypeptide molecular masses ($M_r \times 10^{-3}$) of 7S and 11S globulins present in species

	7S	*11S acidic chain*	*11S basic chain*
Legumes			
Soybean	50, 80	10–40	20
Pea	12–50, 70	25–40	21–22
Peanut	23–75	14–48	21
Lupin	15–60	25–63	21
Oilseeds			
Oilseed rape/canola		30–40	20
Sunflower		32–34	22–27
Pseudocereals			
Quinoa		32–39	22–23
Amaranth	15–90	30–37	18–27
Buckwheat		32–43	20–23

The terms 7S and 11S refer to vicilin-like and legumin-like proteins, respectively, and do not imply that all of the proteins listed have these precise $S_{20,w}$ values. In fact, the true values vary (~7–8S and 11–13S, respectively). It should also be noted that widely different values for polypeptide masses have been reported and those presented here have been selected by the author. The 7S polypeptides include whole subunits and chains released by proteolysis. The acidic and basic 11S chains are generated by proteolysis of a single precursor subunit.

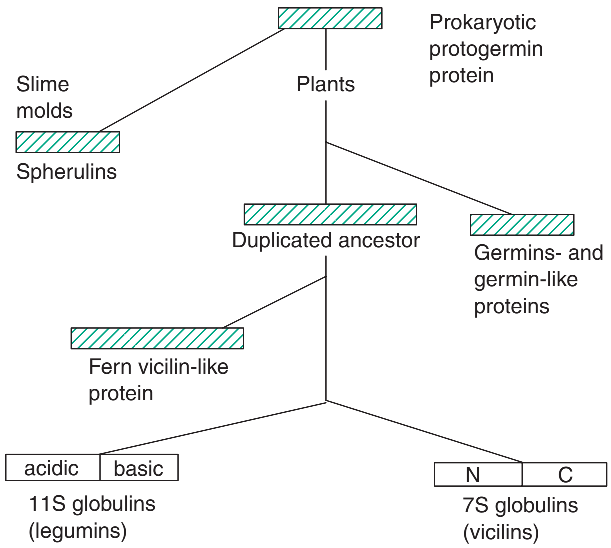

Figure 1 Hypothetic pathway for the evolution of germins and globulin storage proteins from an ancestral "protogermin" protein. (Reproduced with permission from Shewry PR, Jenkins J, Beaudoin F, and Mills ENC (2003) The classification, functions and evolutionary relationships of plant proteins in relation to food allergens. In: Mills ENC and Shewry PR (eds.) *Plant Food Allergens*. Oxford, UK: Blackwell Science.)

more sophisticated comparisons (in which the properties of the amino acids and their propensity to form similar structures are also considered) do indicate some relatedness, particularly between the C-terminal parts of the 7S subunit and the basic chains of 11S subunits. Similar comparisons also show internal homology between the N- and C-terminal parts of the 7S subunits. These observations, and the more detailed structural comparisons discussed below, indicate that the 7S and 11S globulin subunits have evolved from a single ancestral protein that initially underwent a duplication to give two homologous domains which diverged to form the 7S N-terminus/11S basic chain and 7S C-terminus/11S acidic chain, as shown in Figure 1.

Comparisons of the three-dimensional structures of 7S globulin trimers (phaseolin from common bean, canavalin from jack bean, and β-conglycinin from soybean) and the intermediate trimer of proglycinin (the 11S globulin of soybean) confirm this scheme and show remarkable conservation of structure. Each protein consists of three subunits arranged around a threefold axis (Figure 2), with each subunit consisting of two closely related structural modules, and

Figure 2 Structure of the 7S globulin canavalin from jack bean (*Canavalia ensiformis*) seeds. The protein is trimeric, with a single subunit shown in lighter gray. Domains 1 and 3 are β-barrels and domains 2 and 4 α-helical. (Reproduced with pemission from Shewry PR, Jenkins J, Beaudoin F, and Mills ENC (2003) The classification, functions and evolutionary relationships of plant proteins in relation to food allergens. In: Mills ENC and Shewry PR (eds.) *Plant Food Allergens*. Oxford, UK: Blackwell Science.)

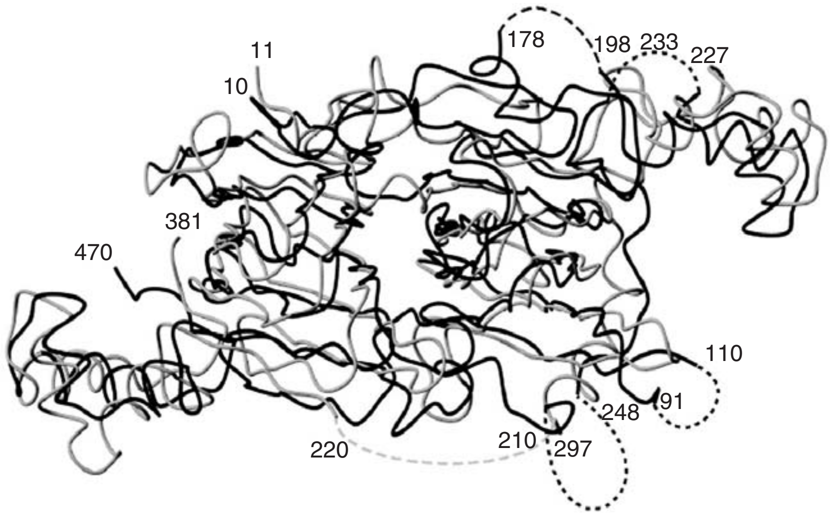

Figure 3 Overlay of the backbone structures of single subunits of proglycinin (11S globulin precursor) from soybean (black) and phaseolin (7S globulin) of bean (gray). (Reproduced with permission from Shewry PR, Jenkins J, Beaudoin F, and Mills ENC (2003) The classification, functions and evolutionary relationships of plant proteins in relation to food allergens. In: Mills ENC and Shewry PR (eds.) *Plant Food Allergens*. Oxford, UK: Blackwell Science.)

each comprising an antiparallel β-barrel domain and an α-helical domain. The subunits of 7S and 11S globulins have similar structures, as shown by the overlay in Figure 3, and the mature hexameric 11S globulin protein is considered to be a "dimer of trimers."

The similarity in the structures of the 7S and 11S globulins is consistent with the observation that both proteins can exist in trimeric forms (the mature 7S and intermediate 11S globulins) and in hexameric forms (the mature 11S globulins and the mature 7S globulins under specific conditions). It is also consistent with the fact that the 7S and 11S proteins appear to be stored as a homogeneous mixture in protein bodies in seeds of legumes and other dicotyledonous species.

A final point of interest is that both 11S and 7S globulins may be allergenic, notably in soybean and peanut.

Albumins

Albumins are defined as proteins that are soluble in water. Consequently, albumin fractions extracted from most plant tissues comprise complex mixtures of largely unrelated components. However, the seeds of many dicotyledonous plants contain a well-defined family of albumin storage proteins with $S_{20,w}$ values of $\sim$2. These "2S albumins" are major storage proteins in a number of dicotyledonous crops (e.g., oilseed rape/canola and sunflower) and minor components in others (e.g., soybean). Although they have not yet been identified in some dicotyledonous crops, this may reflect lack of study rather than true absence, and they may well prove to be ubiquitous in dicotyledonous seeds. A preliminary report of the presence of 2S albumin storage protein in seeds of one monocotyledonous species (yucca) has not been confirmed by more detailed studies, but they are known to be structurally related to several other families of low-molecular-mass sulfur-rich proteins including nonspecific lipid transfer proteins and trypsin/α-amylase inhibitors of cereal grain.

A typical 2S albumin consists of two subunits of M_r $\sim$8–10 kDa and 4–5 kDa, which are associated by two disulfide bonds. However, these two subunits are initially synthesized as a single precursor polypeptide and hence, by analogy with 7S and 11S storage globulins, they should perhaps be called polypeptide chains. Nevertheless, the term subunit is widely used and will be retained here.

The proteolytic processing to release the 2S albumin subunits may result in the loss of short peptide sequences from the N- and C-termini of the proteins and from between the two subunits ("linker" peptides). Furthermore, this proteolysis only occurs after the proproteins are folded and four disulfide bonds formed between eight highly conserved cysteine residues. Two of these become interchain bonds linking the two subunits and two intrachain bonds within the large subunits. This processing is shown schematically in Figure 4. The mature proteins have a compact tightly folded structure comprising five α-helices in a right-handed fold (Figure 5).

The vast majority of 2S albumins have two-chain structures similar to that described above. However, single-chain forms (i.e., without proteolytic processing into two chains) also occur, notably in sunflower.

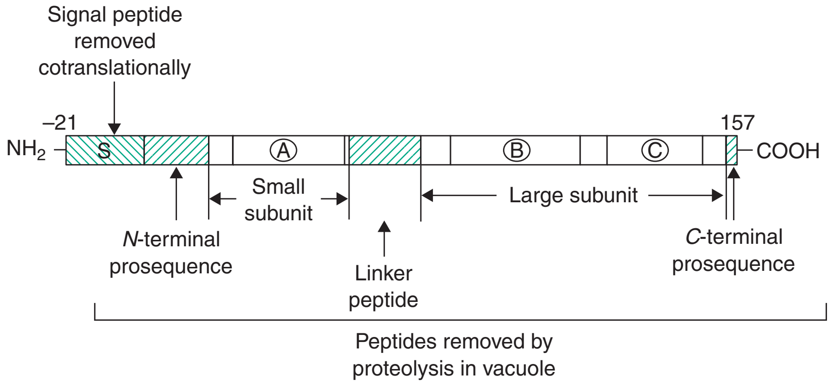

Figure 4 Schematical sequence of the precursor protein of napin (the 2S albumin of oilseed rape) indicating peptides removed by proteolysis and the large and small subunits of the mature protein.

Figure 5 Schematic structure of the 2S albumin from oilseed rape. Alpha helices are shown as cylinders and numbered 1–5. (Reproduced with permission from Shewry PR, Jenkins J, Beaudoin F, and Mills ENC (2003) The classification, functions and evolutionary relationships of plant proteins in relation to food allergens. In: Mills ENC and Shewry PR (eds.) *Plant Food Allergens*. Oxford, UK: Blackwell Science.)

Of particular interest in relation to grain nutritional quality is the presence in some species of 2S albumins that are rich in methionine or, less commonly, cysteine, the two sulfur-containing amino acids that are frequently limiting in legume and other dicotyledonous seeds. These albumins have been studied in most detail in Brazil nut and sunflower. Although they were initially considered to provide an attractive target for use in genetic engineering to increase seed sulfur content, it is now known that both are allergenic, as are 2S albumins from a number of other species (e.g., mustards, castor bean, walnut, sesame seeds, and peanut).

Storage Proteins of Legumes

Many leguminous species store 7S globulin, 11S globulin, and 2S albumin proteins, but the proportions of these vary and exceptions do occur. For example, *Phaseolus* contains 7S but not 11S globulins. Additional types of storage protein also occur in some species, including various lectins and protease inhibitors, which can have negative impacts on nutritional quality.

Soybean is the most widely studied legume species. It contains major groups of 11S (glycinin) and 7S (β-conglycinin) globulins, in ratios ranging from $\sim$1:1 to 6:1 depending on the genotype, with only small amounts of 2S albumins. In addition, a number of other proteins can each account for up to $\sim$5% of the total protein in some lines, notably Kunitz and Bowman-Birk-type protease inhibitors, lectins, urease, and lipoxygenase. Sedimentation coefficients and masses for glycinin have been reported to range from 11.8S to 13.1S and from 30 to 380 kDa and for β-conglycinin from 6.7S to 8.0S and from 105 to 330 kDa.

Glycinin has a typical hexameric 11S globulin structure, with subunits comprising basic chains of M_r $\sim$20 kDa linked to acidic chains varying in mass from $\sim$10 to 40 kDa. Glycinin is also unusual in that the hexamer can undergo reversible dissociation into trimers, depending on the ionic strength. β-Conglycinin comprises various combinations of three major subunits – α (M_r $\sim$80 kDa), α' (M_r $\sim$80 kDa), and β (M_r $\sim$50 kDa) – resulting in seven major forms. Both 7S and 12S globulins of soybean are also thought to be allergenic.

Pea seeds contain legumins (12S to 13S, M_r 330–420 kDa) and vicilins (7S to 8S, M_r 150–190 kDa). The legumin subunits consist of acidic chains of M_r $\sim$25 kDa and 40 kDa linked to basic chains of M_r $\sim$20 kDa. The 7S vicilins comprise subunits of M_r $\sim$50 kDa, but proteolysis at one or two sites and glycosylation at a single site may occur, resulting in polypeptide chains varying in M_r (12–50 kDa). Larger subunits of M_r $\sim$70 kDa also occur, which

form a second trimeric 7S protein called convicilin. Pea seeds also contain two major albumins, PA1 and PA2, of which the former may be a 2S storage albumin. PA1 accounts for ~10% of the total seed protein but half of the total sulfur, in the form of cysteine (~11 mol.%).

The dominant peanut proteins are arachin (13S–14S, M_r 330–400 kDa) and conarachin (8S to 9S, M_r 140–190 kDa). The subunits of arachin comprise acidic chains of M_r ~14–48 kDa linked to basic chains of M_r ~21.4 kDa, whereas conarachin comprises polypeptide chains ranging in M_r from ~23 to 75 kDa. It is probable that both large and typical conarachin subunits are present, as in soybean and pea, with proteolytic processing contributing to the polymorphism. Both proteins also exhibit complex association/dissociation behavior, depending on the ionic strength. The major peanut allergen Ara h 1 is a glycosylated 7S globulin with M_r ~63.5 kDa, whereas Ara h 3 is an 11S globulin.

Most of the knowledge of peanut albumins comes from the analysis of genomic clones and is related to their role as allergens (Ara h 2, 4, 6, and 7). They show high homology to 2S albumins from other legumes (soybean, lupin) and are presumed to have a typical hetrodimeric structure.

The salt-soluble (i.e., albumin and globulin) proteins of lupins are called conglutins. The major component is usually the 7S conglutin β, with slightly less conglutin α (11S globulin) and ~25% of the 2S albumin conglutin δ^-. Conglutin α has a mass of ~336 kDa and readily dissociates to a trimeric form (7.1S, M_r 170 kDa) at low ionic strength or high pH (8.8). It comprises acidic chain varying in M_r (within and between species) from 25 to 63 kDa linked to basic chains of M_r ~21 kDa. Conglutin α is unusual among 11S legumin-type globulins in that it is glycosylated on a single site. Conglutin β comprises polypeptides that range in mass between and within species from ~15 to 60 kDa.

Little detailed work has been carried out on the other legumes/pulses discussed in this article. Both chickpea and lentil contain 11S and 7S storage globulins (in a ratio of ~6:1 in chickpea). In addition, chickpea contains a major albumin of M_r ~20 kDa, which comprises subunits with M_r 10 and 12 kDa.

Adzuki bean is rich in 7S globulins with major components of M_r ~55 kDa, but small amounts of 11S globulins and 2S albumins are also present.

Storage Proteins of Oilseeds

The two most intensively studied oilseeds are sunflower and oilseed rape (canola). Both contain predominantly 11S-type globulins with some 2S albumins.

The 12S globulins (cruciferin) of oilseed rape account for ~40% of the total seed proteins and have M_r of 30–360 kDa. They have a typical hexameric structure with acidic chains of M_r 30–40 kDa linked to basic chains of M_r 20 kDa. The 2S albumins of oilseed rape (napins) also have a typical structure. The major napins have masses of ~14.5 kDa (subunit M_r of ~9 kDa and 4 kDa) but minor forms of M_r ~12.5 kDa also occur. Napin processing includes the loss of N-terminal, C-terminal, and linker peptides, as discussed above.

Sunflower, a member of the family Compositae, contains 12S globulins (helianthinin) and 2S albumins in a ratio of ~2:1. The M_r 300 kDa helianthinin comprises acidic chains of M_r 32–34 kDa (α and α'chains) linked to basic chains of M_r 22–27 kDa (β chains). Sunflower 2S albumins comprise ~11–13 components with masses of 10–18 kDa. All are single chain proteins (i.e., they lack a proteolytic cleavage site between the putative large and small subunits), but most are synthesized as pairs, two albumins being released from a single precursor protein by proteolysis. One sunflower albumin which is synthesized from a separate precursor protein is called SFA8. This contains 16 methionine and 8 cysteine residues in a mature protein of 103 residues (i.e., a total of 23 mol.% of sulfur-containing amino acids). Safflower, a related member of the family Compositae, also appears to contain major groups of 12S globulin (called carmin) and 2S albumin storage proteins but little detailed work has been carried out.

Cottonseed is unusual among nonleguminous dicotyledonous species in containing 7S globulin storage proteins as well as 11S globulins and 2S albumins, with most of the knowledge being based on DNA-derived sequences with little direct analysis of the seed proteins. Linseed (and linola) has not been widely studied but the major seed protein is reported to be a 12.7S globulin of M_r ~250–300 kDa. SDS-PAGE showed six nonidentical subunits.

Storage Proteins of Pseudocereals

Pseudocereals are not true cereals but three dicotyledonous crops that produce small grain-like seeds. Consequently, their seed proteins are similar to those of other dicotyledonous plants rather than related to cereal seed storage proteins.

Seeds of amaranth (*Amaranthus* spp., Amaranthaceae) contain 13S legumin-type globulins (amaranthin) and 8S vicilin-type globulins (conamaranthin). In addition, albumin proteins with $S_{20,w}$ values of ~2 are present, with SDS-PAGE showing major bands of M_r 9 kDa and 4 kDa. This is consistent

with the presence of typical 2S albumins. Two methionine-rich proteins with M_r ~18 kDa have also been reported. Quinoa (*Chenopodium quinoa*, Chenopodiaceae) seeds also contain 11S globulins (chenopodin), of M_r ~320 kDa and 2S albumins, the latter being rich in cysteine (15.6 mol.%) but low in methionine.

In buckwheat (*Fagopyrum esculentum,* Polygonaceae) the major 13S legumin-like globulin is located in the cotyledons with smaller amounts of putative 8S globulins in the perisperm. 2S storage albumins, which are rich in methionine (~9 mol.%), are also present.

Conclusions

The 2S albumins, 7S globulins, and 11S globulins are major groups of storage proteins that are widely distributed in seeds of dicotyledonous plants, although their relative amounts vary and other types of storage proteins also occur in some species. Consequently, they largely determine the nutritional quality and processing properties of the seeds. A detailed knowledge of their structures and properties is therefore essential in order to elucidate structure–function relationships. This will facilitate the optimization of seed quality for traditional and novel products with improvement using classical genetic or genetic engineering approaches.

PROTEIN SYNTHESIS AND DEPOSITION

P R Shewry, Rothamsted Research Station, West Common, Harpenden, UK

Introduction

The protein content of seeds varies widely, from ~10% of the dry weight in cereals to ~40% in soybean. The number of individual protein components present is vast, but all seeds contain well-defined groups of storage proteins, which account for half or more of the total proteins. The storage proteins are largely responsible for the nutritional quality and processing properties of the grain and will, therefore, be the focus of this article.

Four types of storage proteins occur widely in seeds, which were initially defined based on their solubility properties and molecular masses measured by sedimentation equilibrium ultracentrifugation. The latter allows the calculation of sedimentation coefficients ($S_{20,w}$ values) with higher values indicating greater mass. Alcohol-soluble prolamins form the major storage protein fraction in most cereal grain and two types of globulins (7S and 11S), the major fractions in most dicotyledonous species, including legumes and oilseeds. However, many of the latter also contain 2S albumin storage proteins. Similarly, all cereals also contain storage globulins, with proteins related to the 11S globulins of dicotyledonous plants forming the major storage protein group in oats and rice. The characteristics of these four types of proteins

Table 1 Summary of the characteristics of albumin, globulin, and prolamin storage proteins

2S albumins	Soluble in water Molecular mass (M_r) typically ~10–15 kDa Processed post-translationally to give large and small subunits Two intrachain bonds within the large subunit and two interchain disulfide bonds Not glycosylated Specific components are rich in methionine
7S globulins	Soluble in dilute salt solutions Typically trimeric proteins of M_r 150–190 kDa Subunit M_r varies from ~40 to 80 kDa but is typically ~50 kDa Subunits may be proteolytically processed and glycosylated Contain little or no cysteine and methionine
11S globulins	Soluble in dilute salt solutions Typically hexameric proteins of M_r 300–450 kDa. Subunits typically of M_r 60 kDa are post-translationally processed to give M_r 40 kDa (acidic) and M_r 20 kDa (basic) chains associated by one interchain disulfide bond Low in cysteine and methionine
Prolamins	Vary widely in structure, with subunit M_r ranging from ~10–100 kDa Include monomeric forms and high M_r polymers stabilized by interchain disulfide bonds Presence of repeated sequences and regions (domains) rich in specific amino acids results in unusual amino acid compositions Rich in proline and glutamine, poor in lysine and, in some cases, tryptophan, threonine, and methionine No glycosylation or proteolytic processing Soluble in alcohol/water mixture when native and/or reduced

are summarized in Table 1 and the trivial names used for different species in Table 2. This article will focus on their synthesis and deposition.

Synthesis, Folding, Processing, and Deposition of Seed Storage Protein

The vast majority of the proteins present in the mature cereal grain, including all of the major groups of storage proteins, are encoded by genes present on the chromosomes in the nucleus. Smaller genomes are also present in two organelles, the mitochondrion and plastid, but these do not encode any major seed proteins. Initiation of gene transcription is regulated by the interactions between promoter elements located upstream of the gene-coding regions and transcription factors, which are proteins that interact with the promoter elements and with the RNA polymerase enzyme that catalyzes the synthesis of messenger RNA (mRNA) from the DNA template in the gene. The mRNA is initially synthesized as a precursor form which is processed in the nucleus prior to being transported through the nuclear membrane to the cytoplasm for translation.

Protein synthesis involves the translation of the nucleotide sequence of the RNA (which is initially derived from that of the genomic DNA) into the amino acid sequence of the protein. This occurs on structures called ribosomes, which comprise complexes of ribosomal RNA and proteins. Transfer RNAs bearing

Table 2 Types of major storage proteins present in seed crops and their trivial names

Species	*Protein type*	*Trivial name*
Cereals		
Wheat (*Triticum* spp.)	Prolamin	Gliadin/glutenin
Barley (*Hordeum vulgare*)	Prolamin	Hordein
Rye (*Secale cereale*)	Prolamin	Secalin
Corn (*Zea mays*)	Prolamin	Zein
Sorghum (*Sorghum bicolor*)	Prolamin	Kafirin
Oats (*Avena sativa*)	Prolamin	Avenin
	11S globulin	
Rice (*Oryza sativa*)	Prolamin	
	11S globulin	Glutelin
Legumes		
Soybean (*Glycine max*)	7S globulin	β-Conglycinin
	11S globulin	Glycinin
Broad bean (*Vicia faba*)/	7S globulin	Vicilin
pea (*Pisum sativum*)	11S globulin	Legumin
French bean (*Phaseolus vulgaris*)	7S globulin	Phaseolin
Peanut (*Arachis hypogaea*)	7S globulin	Conarachin
	11S globulin	Arachin
Oilseeds	2S albumin	
Cottonseed	11S globulin	Gossypin
(*Gossypium hirsutum*)	7S globulin	Congossypin
	2S albumin	
Sunflower	11S globulin	Helianthinin
(*Helianthus annuus*)	2S albumin	
Oilseed rape/canola	11S globulin	Cruciferin
(*Brassica napus*)	2S albumin	Napin

Table 3 Summary of the major events in protein synthesis from nuclear genes

Genomic DNA in the chromosomes of the nucleus consists of a linear sequence of four nucleotides (bases). Individual genes comprise protein-coding sequences flanked by regulatory sequences. Coding sequences specify the amino acid sequences of proteins in series of three bases called codons. The correspondence of codons to amino acids is called the genetic code. Regulatory sequences control gene expression by interactions with regulatory proteins (transcription factors) and RNA polymerase enzymes.
↓
Transcription of gene gives messenger (m) RNA with codon sequence reflecting that in the gene.
↓
mRNA is processed in the nucleus and transported via nuclear membrane to cytoplasm.
↓
mRNA binds to ribosome in the cytoplasm. Transfer RNAs bearing amino acids recognise and bind to specific codons allowing the amino acids to be linked in a specific sequence by peptide bonds. Thus the sequence of codons determines the amino acid sequence of the protein.
↓
Translation of a signal peptide directs the ribosome to the endoplasmic reticulum (ER) allowing translocation of the nascent protein into ER lumen.

amino acids and mRNAs are brought together on the ribosome resulting in the formation of peptide bonds between adjacent amino acids leading to the synthesis of the polypeptide chain.

Attachment of the mRNA to the ribosome occurs in the cytoplasm and the translated protein may subsequently be released into the cytoplasm. However, many proteins are synthesized with an N-terminal signal peptide, which directs them into the endomembrane system. This is because the translation of the signal peptide causes the ribosome to attach to the outer surface of the endoplasmic reticulum (ER), allowing the signal peptide to direct the nascent (newly synthesized) protein through the ER membrane into the lumen.

The major events in protein synthesis and the way that the sequence of nucleotides in the genomic DNA ultimately determines the sequence of amino acids in the protein, are summarized in Table 3. More detailed and highly readable accounts of the various stages of protein synthesis are given in Buchanan, Gruissem, and Jones (see Further Reading).

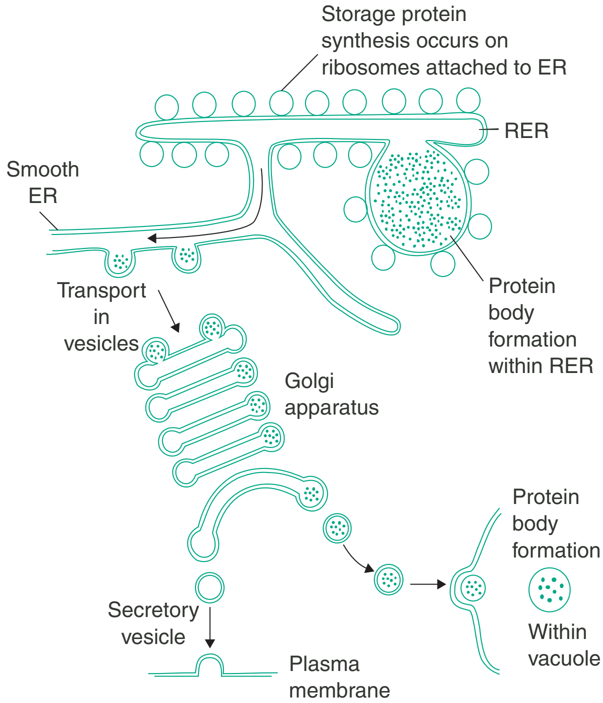

Figure 1 Schematic summary of storage protein synthesis, processing, trafficking, and deposition in the endomembrane system of the cell.

Seed Storage Proteins Are Products of the Endomembrane System

Seed storage proteins are present in the cells in dense protein bodies. These originate from the endomembrane system of the cell, which comprises the ER and structures derived from this, including the Golgi apparatus and various types of vesicle, which transport components to and from specific cellular destinations. The parts of the endomembrane system that are relevant to storage protein synthesis and deposition are shown schematically in Figure 1 while the processing events are summarized in Table 4.

It should be noted that trafficking of proteins through the endomembrane systems is a highly regulated process with the destinations of individual proteins being determined by the presence of specific sequences or structural features. In the absence of such signals, the protein is secreted from the cell, by fusion of "secretory vesicles" derived from the Golgi apparatus with the plasma membrane. Hence, secretion is often referred to as the default destination.

Synthesis, Folding, and Disulfide Bond Formation Occur Simultaneously on the ER

Seed storage proteins are synthesized by mRNA associated with polyribosomes present on the rough ER.

Table 4 Processing of seed storage protein in the endomembrane system of the cell

	ER	*Golgi apparatus*	*Vacuole*
2S albumins	Folding, disulfide bond formation		Proteolytic processing
7S globulins	Folding, N-glycosylation, formation of trimers	Glycan modification	Glycan trimming, proteolytic processing
11S globulins	Folding, disulfide bond formation, formation of intermediate trimers		Proteolytic processing to give acidic and basic chains, formation of hexamers
Prolamins	Folding, disulfide bond formation, polymer assembly		

The protein translated from the mRNA differs from that deposited in protein bodies in the presence of a short N-terminal extension (the signal sequence which is usually ~20 amino acids) whose role is to lead the newly synthesized (nascent) polypeptide through the ER membrane into the lumen, thus entering the endomembrane system. This occurs by specific interaction of the signal sequence with a complex of proteins called the translocon. Once the nascent polypeptide emerges into the ER lumen the signal sequence is removed by a specific enzyme (a signal peptidase) and the polypeptide chain commences to fold into its three-dimensional structure. These events, translocation, signal peptide cleavage and folding, occur when the protein is still undergoing synthesis and hence are termed cotranslational. Protein folding is almost certainly assisted by a complex of proteins and other factors, the most well known of which is the "molecular chaperone" BiP (binding protein). In addition to assisting protein folding, BiP also binds to malfolded proteins to prevent their escape from the ER. Thus, it is often present in higher amounts in mutants in which seed protein synthesis is affected (e.g., *floury-2* and *defective endosperm – B30* of maize) as well as during the period of maximum storage protein synthesis and deposition.

Most proteins synthesized on the ER also contain interchain and/or intrachain disulfide bonds. These bonds also form in the ER as an integral part of protein folding and this may be assisted by the enzyme protein disulfide isomerase (PDI) which catalyzes the formation, exchange or reduction of disulfide bonds, depending on the substrate and conditions.

Storage Albumins and Globulins Are Deposited in Storage Vacuoles

The 2S albumin and 7S and 11S globulin storage proteins are transported via the ER lumen, Golgi apparatus, and vesicles to specialized storage vacuoles where they form dense deposits. These vacuoles may subsequently divide to form protein bodies. However, all three types of storage protein may also undergo modification, either in the vacuole or during their passage through the ER and Golgi apparatus.

The 2S albumins are synthesized as precursor proteins, which undergo folding and disulfide bond formation in the ER lumen. The precursors are then proteolytically processed in the vacuole to generate the mature two-subunit structure. This processing involves cleavage adjacent to specific asparagine residues and the loss of one or more short peptide fragments (from the protein N-terminus, C-terminus, and between the two subunits).

The 7S and 11S globulin subunits are also folded in the ER lumen with the formation of a single intrachain disulfide bond in the latter (7S globulins lack cysteine residues and hence have no disulfide bonds). Both types of subunits are then assembled into trimeric structures stabilized by noncovalent forces. There has been considerable debate about the extent to which globulin storage proteins are modified by the addition of oligosaccharides (glycosylation). It is now established that this rarely, if ever, occurs for 11S globulins but that some 7S globulin subunits are modified by glycosylation of specific asparagine residues (N-glycosylation). This occurs in several stages, with the initial attachment of a high mannose sugar occurring cotranslationally (i.e., concurrent with folding and disulfide bond formation). Subsequently, enzymes present in the ER and Golgi apparatus may act to remove or add further sugar residues to give a more complex structure with final "trimming" occurring within the storage vacuole. Once within the vacuole, the 11S globulins are proteolytically cleaved at an internal asparagine residue to give acidic and basic chains that remain associated by the single disulfide bond formed in the ER. After this proteolytic processing, the "intermediate timers" formed in the ER are able to assemble to form the mature hexameric structure.

The 7S globulin subunits may also be proteolytically processed in the vacuole, but this depends on the species and the precise protein subunit. For example, in bean (*Phaseolus vulgaris*) and soybean (*Glycine max*) the 7S globulin subunits do not undergo any proteolysis, while in pea (*Pisum sativum*) some

subunits are processed at one or two sites to give polypeptide chains ranging in mass from ~12 to 35 kDa, in addition to unprocessed chains of mass ~50 kDa. However, the trimeric structure is not affected by these processing events.

Cereal Prolamins Are Deposited in Two Types of Protein Body

Cereal prolamins do not undergo glycosylation or proteolytic processing (except for cotranslational removal of the signal sequence), but some subunits are assembled into high molecular mass polymers stabilized by interchain disulfide bonds. In wheat, these glutenin polymers may have masses of between 1 and 10 MDa and it is not known how such complex multisubunit structures are assembled. However, it is probable that assembly and interchain disulfide bond formation occur rapidly after synthesis within the ER lumen. Subsequently, prolamins are deposited in two discrete types of protein body.

In rice and maize (and probably also in sorghum and millets), prolamins accumulate directly within the lumen of the ER to form a population of protein bodies surrounded by a membrane of ER origin which may remain studded with ribosomes. In contrast, it appears that two separate pathways occur in wheat, barley, and rye, with some prolamins being trafficked through the ER and Golgi apparatus and deposited in storage vacuoles (as described above for albumin and globulin storage proteins) while others are retained in the ER as in maize and rice. It has been suggested that the polymeric prolamins are preferentially retained in the ER and monomeric forms transported to vacuoles, but it seems likely that the division is not so clear-cut. It is also probable that the relative amounts of prolamins deposited in the two types of protein body vary with the rate of protein synthesis and with the developmental state of the tissue. Thus, it can be envisaged that high levels of protein synthesis would lead to a high level of accumulation within the ER lumen and that this route would also be favored as the cells become distended with deposits of starch and proteins. In wheat, the individual protein bodies collapse during the later stages of seed maturation forming a continuous matrix in the cells of the mature grain.

What Determines the Destination of Storage Proteins in the Endomembrane System?

As discussed above, trafficking through the endomembrane system is a highly regulated process with the destinations of proteins being determined by their sequences and structures.

The retention of storage proteins within the ER or their transport to the vacuole should, therefore, result from the presence of specific signals. A number of proteins are permanently resident in the lumen of the ER, including PDI and BiP. In these cases, retention results from the presence of a specific ER retention signal, which is a tetrapeptide located at the protein C-terminus. The two most widespread tetrapeptides are KDEL and HDEL, which correspond to the amino acids, lysine or histidine, aspartic acid, glutamic acid, and leucine. There is no evidence that such a retention signal is present at the C-termini of prolamins that are retained in the ER and a different mechanism must therefore be sought. It has been suggested that BiP plays a role in rice, by transiently binding to prolamins and retaining them in the ER to allow assembly into protein bodies. However, this mechanism has not so far been shown to be applicable to other cereals. An alternative explanation is that retention results from the insolubility of the proteins in aqueous environments (i.e., the ER lumen) and their propensity to form aggregates under such conditions. It can be envisaged that such aggregates would accumulate directly in the ER lumen and then be "budded off" to form protein bodies.

Some proteins are targeted to the vacuole by the presence of specific "prosequences" which are removed by post-translational proteolysis once the protein arrives in the vacuole. These prosequences may be at the protein N-terminus, as in the barley cysteine proteinase aleurain and the sweet potato storage protein sporamin (which is stored in tubers) or at the C-terminus as in lectins. None of the 2S albumins, 7S globulins, 11S globulins or prolamins that are deposited in vacuolar protein bodies has cleavable prosequences that are involved in vacuolar targeting. However, it has been proposed that aggregation of 7S and 11S globulins into electron-dense aggregates in the Golgi is a prerequisite for ensuring that they are sorted into dense vesicles and ultimately deposited into the vacuole, whereas other proteins are sorted into different types of vesicles with different destinations. This sorting may require the presence of specific hydrophobic residues, which mediate the protein–protein interactions. However, the precise mechanisms that determine the final destination of seed storage proteins, whether to ER-derived or vacuolar protein bodies, are still poorly understood.

Organization of Storage Proteins in Protein Bodies

The 7S and 11S globulins have similar three-dimensional structures with the 11S hexamers essentially corresponding to dimers of the trimeric 7S

proteins. This similarity presumably facilitates their efficient packaging in the same protein bodies. However, protein bodies may also contain separate phases, or inclusions, containing specific proteins or other components. For example, the protein bodies of castor bean consist of a matrix of 2S albumins and other proteins (including lectins) with crystalline inclusions of 11S globulins and noncrystalline globoid inclusions consisting of phytin (calcium and magnesium salts of myoinositol hexaphosphoric acid). Phytin globoids are also present in protein bodies of other dicotyledonous seeds and in aleurone cell protein bodies of cereals. The different routes, taken by prolamins and glutelins (11S globulin homologues) in rice, lead to the formation of two separate populations of protein bodies called PB-I (ER-derived containing prolamins) and PB-II (vacuolar-derived containing glutelins). However, in wheat and oats these two types of protein are located in the same protein body, with prolamin inclusions in a globulin matrix in oats and vice versa in wheat (Figure 2). This segregation has been suggested to result in oats from the fusion of ER-derived protein bodies containing prolamins with vacuolar protein bodies containing globulins.

It has also been shown that different types of prolamin (zein) are concentrated in the outer and inner parts of protein bodies of maize, although in this case the location appears to result from the pattern of development of the bodies in the endosperm cells.

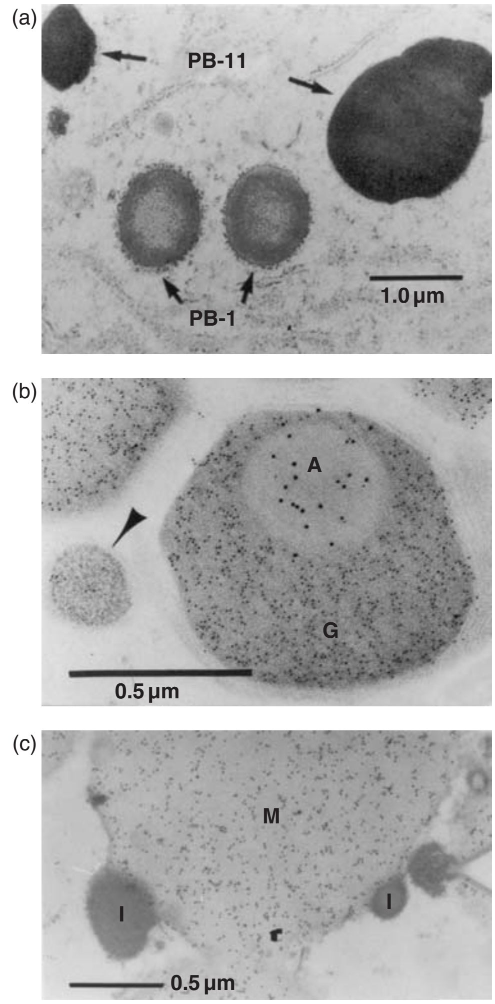

Figure 2 Protein bodies in developing starchy endosperm cells of cereals. (a) Rice at 7 d after flowering, showing two populations of protein bodies. PB-I are spherical vesicles delimited by a single unit membrane derived from the ER and contain prolamins. PB-II are amorphous, derived from vacuolar deposition and contain globulins/glutelins. (b) Oats at 8 d after anthesis showing light-staining deposits of prolamin (labeled with 10 nm colloidal gold) as inclusions in protein bodies containing globulins (5 nm colloidal gold). (c) Wheat at 11 d after flowering showing inclusions of triticin (dark staining, labeled I) within a matrix of prolamin (M). The bars are 1.0 μm in (a) and 0.5 μm in (b) and (c). Regulation of Storage Protein Synthesis

Tissue Specificity

Storage protein synthesis in seeds is strictly regulated with respect to timing, tissue specificity and, to a lesser extent, nutrient availability. In addition to the embryo, which is a diploid zygotic tissue that gives rise to the seedling, all seeds also contain an endosperm, which is triploid and is derived from a second fertilization event. However, the size of the endosperm varies greatly, forming 80–90% of the mature cereal grain but being largely broken down during development in soybean and many other seeds. Similarly, whereas some seeds such as quinoa and amaranth contain a perisperm (derived from the maternal nucellar tissue), this fails to develop and is absorbed in most species. In all seeds, at least one of these three tissues functions as a storage tissue, and in some cases more than one. The central part of the endosperm is the major storage tissue in cereals, accumulating protein (prolamins with varying amounts of 11S-type globulins) and starch. However, 7S globulins and oil are also stored in the outer cells of the endosperm (the aleurone layer) and the single cotyledon (scutellum) of the embryo. The cotyledons of the embryo form the major storage tissue in grain legumes (including soybean, peanut, lupin, and pea), sunflower and

oilseed rape/canola while proteins and oil are stored in the endosperm and embryo of quinoa with starch being stored in the perisperm.

It should also be noted that the synthesis of seed storage proteins has never been detected in nonseed tissues of the plant, whether by determining gene expression (i.e., mRNA populations) or protein accumulation.

Temporal Regulation

Seed development proceeds through a series of genetically programmed stages, starting with cell division and differentiation to establish the basic structure of the component organs and tissues (i.e., the embryo, endosperm etc.). The synthesis and accumulation of storage products, including proteins, occurs during the subsequent expansion of the cells of the storage tissue(s) and ceases when these cells mature and desiccate. The onset and duration of the phases varies widely between species and genotypes and is greatly affected by the environmental conditions. In small grain cereals (wheat, barley) grown in the UK, storage protein synthesis is usually first detected in appreciable amounts at ~12–14 days after pollination and is most active over the next 2–3 weeks. However, synthesis may be initiated as early as 6 days in plants grown in hot, dry climates. In maize (corn) grown in North America, storage protein synthesis occurs between ~3 and 7 weeks after pollination.

Storage protein fractions are, of course, not single proteins but mixtures of components, which may be encoded by several multigene families. In general, these genes show highly coordinated patterns of expression, with only small differences in their timing and relative levels of expression during development. For example, in sunflower the expression of genes for 11S globulin storage proteins (helianthinins) is detected slightly before that of genes for 2S albumins, but in wheat and the barley transcripts for all groups of prolamin storage proteins show similar expression patterns.

Environmental Control

Environment has a major impact on seed development, including storage protein synthesis, with higher temperatures generally increasing the rate of development. In addition, specific heat-shock effects may occur when temperatures exceed ~35°C – these can result in detrimental effects on the quality of wheat grown in Australia and some other parts of the world. The most dramatic effect of environment on storage protein synthesis is that of nutrition. It is well established that the protein content of seeds is regulated by the availability of nitrogen, with storage protein acting as a sink for nitrogen, which is not required by the plant for other purposes. For example, increasing the total nitrogen content of barley grain from ~1% to 3% is associated with an increase in prolamin (hordein) storage proteins from ~35% to 50% of the total grain nitrogen. This effect can be exploited to grow grain with defined protein contents for specific end uses (e.g., low protein for malting barley, high protein for bread-making wheat).

However, almost all storage proteins also contain sulfur in the form of the amino acids cysteine and methionine. Many species are able to adjust to variation in the relative availabilities of nitrogen and sulfur by having specific types of seed storage proteins with high and low contents of sulfur amino acids. Thus, the 2S albumin storage proteins of oilseed rape and sunflower have higher contents of cysteine and methionine than the globulin storage proteins and the synthesis of the former is therefore reduced under conditions of low sulfur availability (Figures 3a and 3b). Similarly, restricted availability of sulfur favors the synthesis of the sulfur poor C hordeins of barley (Figure 3c) and ω-gliadins of wheat over other more sulfur-rich prolamins, which can have adverse consequences for grain quality in the latter species.

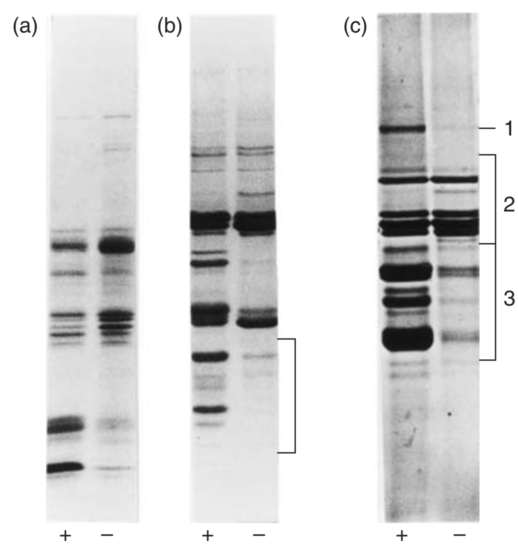

Figure 3 The effect of sulfur on the total seed proteins of oilseed rape (a) and sunflower (b), and on the prolamin (hordein) proteins of barley (c). Note the presence of S-rich low molecular mass proteins (probably 2S albumins) in oilseed rape and sunflower (bracket) and of S-poor C hordeins (2) in barley. Parts (a) and (b) are reproduced with permission from Spencer D, Rerie WG, Randall PJ, and Higgins TJV (1990). Regulation of Storage Protein Gene Expression

The regulation of seed storage protein genes usually occurs at the level of gene transcription, although some "fine tuning" can occur at the level of translation of the mRNA into proteins. Consequently, interest has focused on the identification of regulatory sequences present upstream of the gene sequences that encode storage proteins (called 5′ upstream sequences) and of specific proteins that bind to these (transcription factors). This has led to the identification of short conserved nucleotide sequences (often called boxes) that regulate expression of the genes.

Comparison of the 5′ upstream sequences of a number of genes encoding 11S storage globulins has led to the identification of a 28 base pair (bp) "legumin box." Deletion of a central 7-nucleotide motif from the center of this box resulted in a drastic reduction in the gene expression in transgenic plants, demonstrating its importance. Related "boxes" are also present in the 5′ upstream sequences of 7S globulin and 2S albumin genes. However, further studies have demonstrated the presence of several additional upstream regulatory sequences that may modulate storage globulin gene expression.

Similar studies have shown that many prolamin genes also contain a conserved sequence of ~30 bp located about 300 bp upstream of the gene-coding region. This is called the "endosperm box" or "prolamin box" and is unrelated in sequence to the "legumin box." The "prolamin" box actually comprises two conserved sequences separated by a more variable region. One of these conserved sequences is thought to be responsible for conferring endosperm-specificity while the other may play a role in the regulation of the gene. However, additional regulatory sequences are undoubtedly also present including a short sequence (the E motif) in the α-zein genes of maize, which binds the protein encoded by the *Opaque 2* locus. Mutation of this locus results in reduced α-zein synthesis and a "high lysine" phenotype. Although several other proteins that bind to regulatory sequences of storage protein genes have also been identified, the precise mechanisms of storage protein gene regulation remain poorly understood.

Conclusions

It is clear that we still have much to learn about the precise mechanisms of storage protein synthesis, trafficking, and deposition, although the broad principles are now understood. A detailed understanding of these mechanisms is important as interactions (i.e., between proteins and with other grain components) established during synthesis and deposition may ultimately affect the functional properties of the proteins in food products. Furthermore, it is becoming clear that the synthesis, assembly, deposition, and interactions of seed proteins may be affected by environmental factors that ultimately impact on seed quality. Identifying the major sites of these effects and the critical stages of seed development should allow them to be predicted and ultimately manipulated give a higher level of stability.

It is also important to understand the mechanisms of seed protein synthesis, trafficking, and deposition in order to facilitate the application of genetic engineering to improve grain quality. It is essential that any novel or mutant proteins expressed in transgenic plants should be "accepted" by the secretory system as authentic and transported to their correct destination. Any errors in folding or failure to contain the correct targeting information could lead to protein turnover or accumulation in incorrect compartments (e.g., ER instead of storage vacuoles in dicotyledonous seeds) with adverse effects on grain development, quality, and yield.

C Wrigley, Food Science Australia and Wheat CRC, North Ryde, NSW, Australia

Introduction

Elucidation of grain composition at the molecular level is needed to permit ongoing genetic improvements to grains with respect to their efficient production and processing. This information is especially needed concerning the proteins of the grain, because they are the primary molecules in implementing the "directions" from the relevant genes, under the further control of environmental conditions. There is thus an important interaction between genotype (the variety, the set of genes) and growth conditions (Figure 1), and this interaction determines the synthesis of the individual proteins that are needed to conduct all the functions of the plant cells.

Background to Proteomics

The study of proteins and their functions has long been an accent of biochemical research, but it has been only in the 1990s that the concept of "proteomics" has been introduced to this study. Proteomics is a powerful approach to the analysis of gene expression in biological systems, with the term "proteome" indicating the full complement of proteins expressed by the genome of an organism (e.g., wheat) in a tissue (e.g., leaf, endosperm, or embryo) at a particular stage of development and under specific growth conditions. Studies of the proteome and the genome complement each other (*see* **Genomics**). The genotype is defined by the complete set of genes that constitute the genome of an organism (a grain-producing plant for current discussions). Although the complete genome is present in every cell of the plant, only those genes appropriate to a specific tissue are active there, e.g., in the roots or in the leaves. The specific genes that are active are also determined by the growth conditions, as shown in Figure 1.

The first activity of the genes is transcription, i.e., the production of messenger ribonucleic acid (mRNA), with a nucleotide sequence based on that of the stretch of DNA that constitutes the particular gene. Analysis of the mRNA (the "transcriptome") provides information about which proteins are to be synthesized in the next stage of translation (*see* **Protein Synthesis and Deposition**), as shown in Figure 2. Routinely, analysis of the proteins (the proteome) is preferred over study of the mRNA, because the mRNA molecules are transitory, being degraded after their role in protein synthesis is completed. Therefore, the mRNA transcripts may not be a true indicator of protein expression, and often do not correlate with protein levels.

The transcriptome and the proteome are thus subsets of the wider range of mRNA and protein molecules that might have been produced, given the full extent of the genome. In summary, study of the proteome tells us about the range of proteins that relate to the specific tissue under study (root or shoot or mature grain), as it was grown under the particular

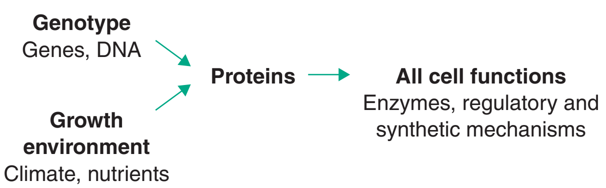

Figure 1 The interaction of genotype and growth conditions to affect the protein composition.

environmental conditions existing at the time for the genotype involved.

Methods of Proteome Analysis

The various aspects comprising proteome technology are illustrated in Figure 3 – including, the preparation and extraction of proteins, the fractionation of proteins using the "core" separation technique of two-dimensional gel electrophoresis (2-DE), image analysis and subsequent characterization, and identification of proteins using micro-analytical techniques combined with protein-sequence database interrogation.

Figure 4 provides an example of a proteome map. This shows the proteome of the floury endosperm of Wyuna immature wheat grain (mid-development, 17 days postanthesis; DPA), obtained by extracting the proteins from the sample of grain endosperm, fractionating them in the first dimension according to their isoelectric points in two parts. The second-dimension fractionation resolved the proteins according to their sizes (largest at the top). Each spot represents a single protein (polypeptide). Numbered spots have been cut out of the second-dimension gel, eluted from the gel piece, and analyzed to characterize their N-terminal amino-acid sequence, which was then used to interrogate protein sequence databases to determine their likely identity. Table 1 shows the results of identifying some of the protein spots. Figure 4 and Table 1 illustrate the three main steps of proteome analysis, namely, sample preparation, protein fractionation, and component characterization and identification.

Preparing Samples for Two-Dimensional Electrophoresis

Sample preparation is critical in obtaining reproducible and high-resolution gels. Prior to the extraction and solubilization of proteins, tissues are often treated for the removal of cell components, which can exert deleterious effects during extraction (such as salts, lipids, organic acids, phenolic compounds, and pigments). An example of this treatment is the precipitation of proteins from plant tissues using trichloroacetic acid (TCA) and acetone, resulting in the removal of most of these undesirable components.

Proteome studies of wheat have involved the extraction and solubilization of proteins in a buffer consisting of 7 M urea, 2 M thiourea, 2 mM trybutyl phosphine (TBP), 4% 3-((3-cholamidopropyl)-dimethylammonio)-1-propane sulfonate (CHAPS), 1% carrier ampholytes, 40 mM tris, and a trace amount of Bromophenol blue dye. The urea and thiourea are chaotropic agents, denaturing the protein molecules. The zwitterion detergent (CHAPS), combined with the chaotropic agents, aids in the solubilization of proteins. The reducing agent TBP

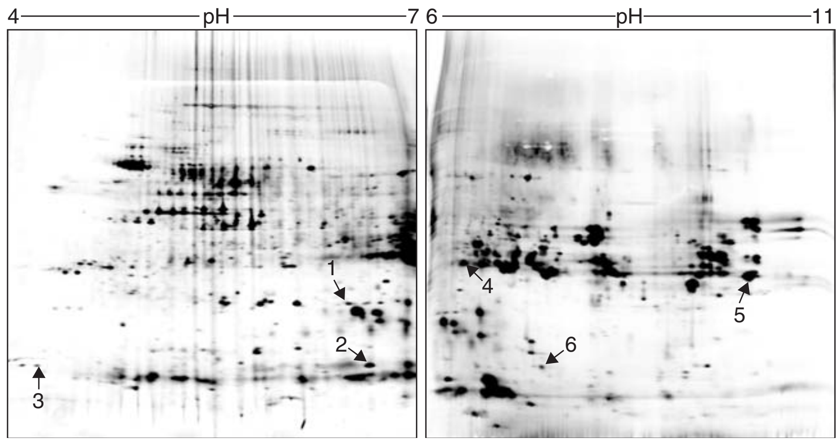

Figure 4 The acidic and basic proteome maps of immature (17 DPA) wheat-grain endosperm of the soft Wyuna variety. Protein spots were characterized by N-terminal amino acid sequencing and identified from protein-sequence database interrogation. Protein identities are described in Table 1.

Table 1 N-terminal amino acid sequence characterization of immature wheat endosperm proteins

Spot no.	*N-terminal sequence*	*Gene product*	*Identity (%)*	*Matched organism*	*Comments and accession no.*
1	XATFTLPD	Superoxide dismutase (EC 1.15.1.1)	87.5% in 8 aa	Wheat	N-terminal sequence starts at residue 22 of O82571 with residues 1–21 possibly being a signal sequence or truncated. Also matches to P93606 and Q96185
2	SGPWMCYV	α-Amylase inhibitor WDAI-3	100% in 7 aa	Wheat	P10846 (fragment). Also matches other α-amylase inhibitors P01084 and P01085
3	MKLIAAYL	60 S acidic ribosomal protein P2 (ribosomal protein “A”)	100% in 8 aa	Wheat	Subunits P1 and P2 exist as dimers at the large ribosomal subunit P05390
4, 5	NMQVDPSG	γ-Gliadin	100% in 8 aa	Wheat	N-terminal sequence starts at residue 20 of P21292 as signal sequence of precursor is residues 1–19
6	DILRSDQP				No close matches

Protein sequences were used to interrogate SWISS-PROT and TrEMBL databases via FASTA algorithm.

is noncharged and breaks the disulfide bonds existing in many proteins, producing individual polypeptides. TBP does not migrate out of the first-dimension immobilized pH gradient (IPG) strip during the course of isoelectric focusing (IEF), allowing the proteins to remain in their reduced state as separate polypeptides. The trace amount of Bromophenol blue dye is used as an indicator of current during IEF, migrating off the IPG strip due to the negative charge of the dye.

Two-Dimensional Gel Electrophoresis

The resulting protein extracts are fractionated to provide a 2-DE protein map. The first dimension involves IEF, in which proteins are fractionated across a specific pH range using commercially available IPG strips. Proteins in the IPG strip migrate and resolve to the point at which they have a zero net charge, which is known as their isoelectric point (pI). The second-dimension fractionation resolves the proteins on the basis of molecular mass, using sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE). The SDS detergent binds to the denatured proteins, overriding any intrinsic charge differences, to provide a uniform charge-to-mass ratio, allowing proteins to resolve according to their respective sizes.

The 2-DE proteome map in Figure 4 represents the proteins of immature wheat grain flour. It shows the polypeptides extracted from the immature endosperm of the soft wheat variety “Wyuna,” the endosperm being the floury part of the grain, excluding the germ, embryo, and bran layers (*see* **Grain and Plants, Morphology**). The proteome map of Wyuna appears in two parts, reflecting two different pH ranges used in IEF. Protein extracts were fractionated in both acidic (pH 4–7) and basic ranges (pH 6–11). The

proteome pattern is thus a map of isoelectric point (pI), in the horizontal dimension increasing from left to right, and of molecular size in the vertical dimension. SDS-PAGE provides fractionation on the general basis of the size of the protein molecules, from largest (top) to smallest (bottom). After 2-DE fractionation, the proteins in the gels must be visualized. There are various stains available for protein visualization, including "silver staining," but the more common and routinely used stains now are fluorescent dyes, such as SYPRO Ruby protein stain. This stain is commercially available, ready-to-use, ultrasensitive and compatible with subsequent protein characterization methods.

The two proteome maps in Figure 4 show that a large number of polypeptide spots has been resolved. About 1300 protein spots can be counted using specialized image analysis software. There are many more that are faint or difficult to discern with certainty, due to their low concentration or poorer resolution, or because of the presence of overlapping components. The number of proteins actually visualized also depends on the affinity of the individual proteins for the dye used.

Characterization and Identification of Protein Spots

This procedure of 2-DE has been available for some decades. The relatively novel aspect of proteome analysis is the subsequent stages of postseparation microcharacterization of the individual protein spots. The ability to characterize and identify proteins in a high-throughput manner is a critical factor in proteome projects. Two widely used protein-characterization methods are N-terminal amino acid sequencing and mass spectrometry (MS), with the latter being the preferred method of choice used in proteome projects.

N-terminal amino-acid sequencing has been a popular method for characterizing proteins in the past. The most common form of this method is the traditional Edman degradation chemistry, which can be used to sequence proteins from gels, or it can be carried out on proteins electroblotted from the proteome gel to a polyvinylidene difluoride (PVDF) membrane. In either case, Edman chemistry involves the reaction of phenylisothiocyanate with the free amino group of the protein; derivatives are cleaved, then converted to phenylthiohydantoins, which differ in their amino-acid side chain, allowing them to be characterized by retention time using reversed-phased high-performance liquid chromatography. This is not the preferred method in high-throughput large-scale proteome projects, due to the relatively low number of samples that can be processed in parallel (generally only three or four samples), its low sensitivity, and the time and cost for analysis. This method of characterization is useful when studying proteins from poorly defined genomes. Examples of proteins characterized and identified by N-terminal sequencing and protein-sequence database interrogation are provided in Table 1.

Due to the recent emphasis on high-throughput protein characterization, traditional amino-acid sequencing has been superseded by mass spectrometry (MS). Generally, MS can be used to (1) determine the composition of the polypeptide analyte (when run in MS mode), by measuring the mass values of peptides generated by enzymatic digestion of the protein from the gel, and (2) determine the primary structure of selected peptides, by fragmenting a selected peptide in order to deduce the amino-acid sequence, a technique known as tandem MS (MS/MS). When running in the MS mode, two particular techniques are commonly used for protein characterization. The first technique is matrix-assisted laser desorption/ionization (MALDI) MS, and the second is electrospray ionization (ESI) MS. In the MALDI-MS method, ions are generated from solid-phase samples in a high vacuum by a short laser pulse. These ions are accelerated by an electric field into a time-of-flight (TOF) analyzer, giving rise to the term MALDI-TOF MS.

In this technique, the flight time of an analyte is proportional to the mass-to-charge ratio. Therefore, the mass-to-charge ratio of an unknown analyte can be deduced by calibrating the instrument with an analyte with known mass. In the case for ESI-MS, the ions are generated from a liquid phase, which is thought to occur by residual solvent evaporation or field desorption. In this technique, the mass analyzer is usually an ion trap, quadrupole or an ion cyclotron analyzer. Both MALDI and ESI are the preferred methods for the ionization of peptides and proteins. When running MS/MS mode, the analyte is measured in terms of mass, and then selected for fragmentation, usually by collision-induced dissociation (CID) within the mass spectrometer. This method produces primary structure information, which can then be used to identify the protein of interest from protein-sequence databases.

Routine protein identification in high-throughput proteomic projects is usually accomplished using MALDI-TOF MS peptide-mass fingerprinting (PMF), which involves the enzymatic digestion of proteins, giving rise to a unique subset of peptide masses. This can be achieved using a range of enzymes, the most common being trypsin, cleaving specifically at the C-terminal side of lysine and arginine amino-acid residues. The generated subset of polypeptides can

then be used to interrogate theoretically derived peptide-mass fingerprints of proteins in protein-sequence databases. If the protein is not present in the databases, or the PMF data are not sufficient for an unambiguous identification, tandem MS is used to generate amino-acid sequence information to search protein databases. Furthermore, MS strategies have been developed to detect post-translational modifications of proteins, such as glycosylation and phosphorylation of proteins. An example of protein characterization and identification using PMF is described in Figure 5.

The Potential Value of Proteomics to Grain Science

The great promise of proteome analysis is that we can identify the individual proteins that are responsible for specific aspects of the phenotype, i.e., the many different characteristics of the plant, and of the grain produced from it. Take the example of a plant breeder who wishes to select for genotypes that have resistance to a specific pathogen, e.g., the rust fungus that attacks the plant, thereby reducing yield of grain. Conventionally, the breeder grows up a large number of genotypes as plants, which must be inoculated with the rust spores. Those that demonstrate resistance are selected. This process is time- and labor consuming. If, on the other hand, we knew the specific proteins that are responsible for conferring rust resistance, analysis of protein composition might be used to identify the resistant genotypes much more quickly and efficiently. To achieve this outcome, proteome analysis might be applied to the leaf proteins of a set of genotypes of defined resistance or susceptibility, searching for specific proteins that might serve as markers of resistance. The added value of this approach would be to use the information in selecting suitable parent lines for ongoing breeding. The approach would also be integrated with complementary studies at the genome level, searching to identify the genes responsible for the synthesis of the marker proteins. Some of these concepts are ideas that have not yet achieved reality, whereas there are many cases where proteome technology has already proved valuable.

Relationship between Proteome and Transcriptome Results

In one particular study, the relationship between the wheat grain endosperm transcriptome (mRNA transcripts) and the proteome (proteins) was investigated. In this study, total RNA extracted from grain, harvested at 4, 6, 8, 10, 12, 15, 18, 21, and 25

days after flowering (days post-anthesis, DPA), was analyzed, after size separation and transfer to nylon membrane, to determine the timing of mRNA transcription from a range of genes during seed development. In particular, the accumulation of the high-molecular-weight glutenin subunit mRNA transcripts and gliadin mRNA transcripts was investigated (*see* **Cereals**: Protein Chemistry). This analysis indicated that significant levels of mRNA from seed storage proteins do not accumulate until after 12 DPA. Gene expression was also investigated for a number of enzymes associated with starch and protein biosynthesis. As an example of this, protein disulfide isomerase, an enzyme involved in protein folding, showed significant transcription as early as 6 DPA, with transcript levels declining significantly by 18 DPA.

As a result of these analyses, a cDNA library was constructed from mRNA isolated from endosperm tissue at 8, 10, and 12 DPA. The total number of active genes in the 8–12 DPA endosperm tissue was estimated. The minimum and maximum limits from these analyses were 4500 and 8000 genes being active. Thus, the average number of different proteins being expressed in the endosperm tissue was 6250. By contrast, proteome analysis of Wyuna endosperm tissue at this same stage of development showed that ~1700 protein spots could be detected from 2-DE gels. These findings suggest that ~27% of the genes expressed in the wheat endosperm could be detected from 2-DE proteome gels. Many reasons may account for the fact that only a portion of the expressed genes could be visualized on 2-DE gels. These include the poor extractability of the more hydrophobic proteins (such as membrane proteins), the fact that some proteins can remain in the IPG strips and do not migrate into the second dimension SDS-PAGE gel, and the sensitivity limitations of protein visualizing stains, in terms of the lower abundance proteins.

Characterization of Wheat Endosperm Proteins during Development and Maturity

Proteomic technology has proved to be a valuable tool in the characterization of protein composition in the developing (17 DPA) and mature (harvested, 45 DPA) wheat grain endosperm. In such studies, many proteins (over 300) from the immature endosperm were characterized by N-terminal amino-acid sequencing and identified from protein-sequence databases, resulting in a detailed proteome map for this wheat cultivar. From these analyses, 55% proteins were identified from database matches, 17% proteins were not matched (they were previously unidentified proteins), and 28% of the proteins produced no sequence information. The most abundant endosperm proteins identified in this study at 17 DPA belong to the seed-storage gliadin and glutenin families, α-amylase inhibitor and α-amylase/trypsin inhibitor families, and the protein disulfide isomerase families. Different subclasses of proteins were observed in some of these protein families. The abundance of these particular families is to be expected at this stage of development. A significant finding of this study was the identification of multiple forms of proteins in these abundant families, as well as in other less abundant protein families. These multiple forms may be attributed, at least in part, to post-translational modifications, although the hexaploid nature (designated A, B, and D genomes) of common bread wheat cultivars increases the complexity of the situation (*see* **Wheat**: Genetics).

The synthesis of seed storage proteins commences at ~10–12 DPA, the proteins being deposited in the endosperm, to provide a source of nutrients and energy for the new plant. The mechanism of deposition is important for elucidation of the dough-forming properties of the storage proteins, given the importance of disulfide-based polymerization of glutenin subunits of the gluten complex. At 17 DPA, protein disulfide isomerase was abundant in wheat endosperm; this enzyme catalyzes the formation of inter- and intra-chain disulfide bonds, required for the correct folding of newly synthesized proteins (*see* **Protein Synthesis and Deposition**). Two forms of protein disulfide isomerase were expressed, which differed in the number of alanine residues in the N-terminus (EEAAAAEE and EEAAAAAEE). These differences may be explained by the control of two separate genes for PDI being expressed at 17 DPA, which could signify the crucial importance of this enzyme to the synthesis and deposition of proteins in the endosperm. Figure 6 depicts the major classes of proteins identified in immature wheat grain endosperm studies so far.

Protein expression within the endosperm at both immature and mature stages of grain growth were compared to gain an insight into developmental changes in protein composition. An example of these developmental changes can be described in the case of the protein disulfide isomerase enzyme. This enzyme was characterized and identified in the immature grain endosperm of 17 DPA, and expression of this enzyme was monitored at maturity (Figure 7). At 17 DPA, when the wheat plant is actively synthesizing many proteins, abundant isoforms of protein disulfide isomerase were present in the endosperm. With the decrease in protein synthesis at maturity, some of the isoforms of protein disulfide isomerase were no longer detected in the endosperm.

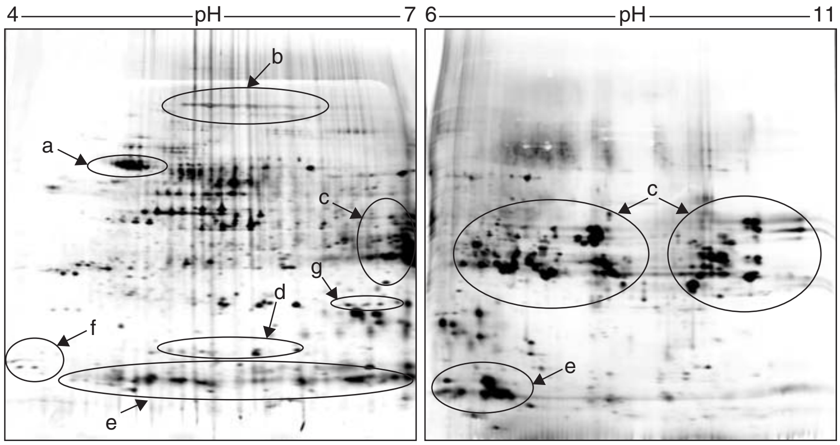

Figure 6 Proteome maps of immature Wyuna endosperm proteins at 17 DPA, including acidic (pH 4–7) and basic (pH 6–11) ranges. Particular protein regions, based on previously reported data, were designated on the 2-DE gels. These protein regions correspond to (a) PDI isoforms, (b) high-molecular-weight glutenin subunits, (c) gliadins, (d) small heat shock proteins, (e) α-amylase/trypsin inhibitors, (f) acidic ribosomal proteins, and (g) superoxide dismutase isoforms. (Reproduced with permission from Cornish GB, Skylas DJ, Siriamornpum S, Bekes F, Larroque OR, Wrigley CW, and Woottom M (2001) Grain proteins as markers of genetic traits in wheat. *Australian Journal of Agricultural Research* 52: 1161–1171.)

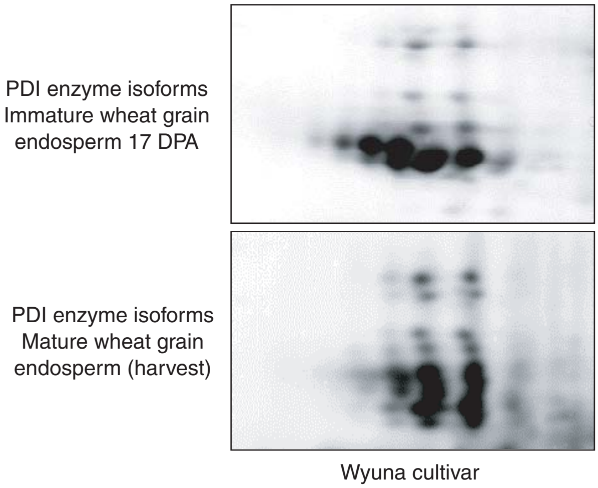

Figure 7 Comparison of PDI expression in immature (17 DPA) and mature (harvested) wheat grain endosperm.

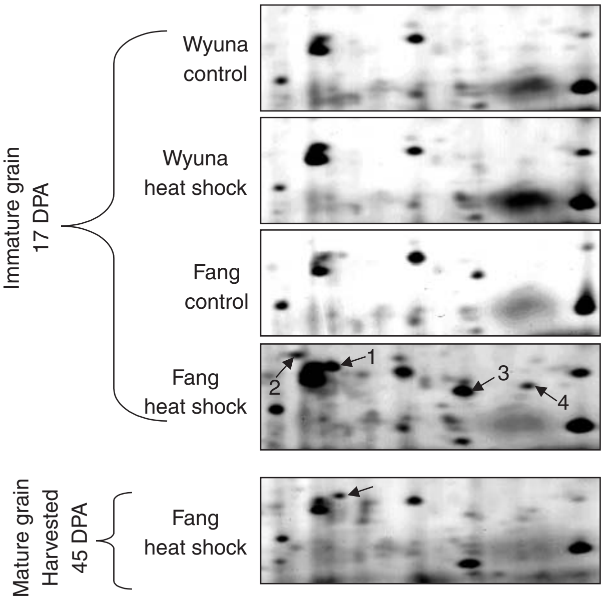
This approach provided extensive information about protein composition in the endosperm, and about changes that occur during development.

Identification of Endosperm Proteins Associated with Heat Tolerance

Another example showing the value of proteomics is in the identification of proteins associated with tolerance to stress conditions during growth. Proteome analysis shows the results of the interaction between the genes (the genome) and the growth environment (e.g., climatic conditions). As mankind has extended the cultivation of grains into climates not ideally suited to them, there have been attempts to breed genotypes (varieties) with tolerance to the stresses imposed. Such stresses include heat (a few very hot days or prolonged heat), frost and drought, as well as a range of pests and pathogens.

In this study, proteome technologies were used to determine the effects of heat shock on endosperm protein expression for the heat-susceptible Wyuna and heat-tolerant Fang cultivars. Wheat plants were grown at day/night temperatures of 24/18°C during development, with stressed plants subjected to heat shock at day/night temperatures of 40/25°C for 3 days in duration, namely, at 15, 16, and 17 DPA. Grain samples were taken during development (17 DPA) and at maturity (harvested grain at 45 DPA). Comparisons were made between these two wheat cultivars differing in heat tolerance, on the basis of rheological properties of dough prepared from the cultivars. Heat-susceptible Wyuna and heat-tolerant Fang cultivars were selected based on previous assessments of these wheats, in terms of heat tolerance and dough rheology. Proteome analysis was conducted on normal and heat-stressed endosperm tissue at the immature (17 DPA) stages of grain development. The heat-shocked Fang cultivar induced or up-regulated the expression of a small number of proteins, which were not detected in the heat-shocked Wyuna cultivar. Four of these expressed protein spots (indicated in Figure 8) were matched to plant small heat-shock proteins (HSP) by searching protein-sequence databases. Proteome analysis was also conducted on endosperm tissue from heat-shocked mature grain (45 DPA) in order to monitor the expression of the candidate marker proteins that were identified at the immature 17 DPA stage of development. As shown in Figure 8, protein spot number 1,



Spot #1 matched to a 16.9 kDa HSP from wheat
Spot #2 matched to a 18.1 kDa from *Medicago sativa* (alfalfa)
Spot #3 matched to a 16.9 kDa HSP from wheat
Spot #4 matched to a 16.9 kDa HSP from wheat

Figure 8 Comparison of control and heat-shocked immature wheat endosperm for the Fang (tolerant) and Wyuna (susceptible) wheat varieties. Candidate marker proteins for heat tolerance, identified at 17 DPA, were monitored at maturity for the heat-shocked Fang variety.

characterized and identified from heat-shocked Fang immature grain, is still detected at maturity. Consequently, this protein would be the best candidate, based on this study, to further investigate as a marker protein, in order to indicate whether or not a grain sample had been exposed to some form of heat stress in the field, and also to indicate if the grain is from a heat-tolerant wheat genotype.

Cultivar Discrimination

The grain proteome has also been investigated as a basis for devising more efficient methods of discrimination between varieties (*see* **Variety Identification of Cereal Grains**). Four wheat cultivars (Halberd, Cranbrook, CD87, and Katepwa) were selected on the basis of differences in their quality, in terms of dough-processing attributes that can suit one cultivar better than another for specific types of industrial utilization. Three particular regions of the proteome were compared in close detail, representing three different classes of proteins: high-molecular-weight polypeptides of glutenin, gliadins, and small heat-shock proteins (based on previous protein identifications). Cultivar-specific proteins were observed in each of these regions, providing information on the extent of grain protein polymorphisms in commercial wheats.

Improving on Current Proteome Technology

At present, 2-DE is the core technology for arraying proteins in proteome projects. However, there are limitations to proteome studies at all stages of the 2-DE process. These limitations need to be overcome, or at least minimized, for this technology to be applied in a more effective manner for discovery in proteome analysis. Technological advances are required, in the areas of sample preparation and 2-DE, to increase the number and type of proteins visualized, so as to include polypeptides that may now be excluded, such as high-molecular-weight, membrane and low-abundance proteins. Recent improvements in increasing the levels of proteomes visualized on the 2-DE gels are a result of the continual development of sequential protein extraction methods and the commercial availability of narrow range IPG strips. A combination of sequential protein extractions and broad and narrow IPG strips allows for a "subproteomic" analysis, in which many more, especially low-abundance and hydrophobic proteins, have a better chance of being visualized using 2-DE gels.

Future Prospects

Further potential in applying the proteome approach to cereal-based research is enormous, with the possibility of future work being based on genotype and environmental interactions, and how these interactions effect the wide range of quality attributes that are relevant to marketing and the many forms of processing. These studies would probably take the form of identifying and establishing protein-marker-based systems, for the selection of desirable genotypes for processing requirements.

With the completion of the first plant-genome sequencing initiative for *Arabidopsis thaliana*, and progress with other plant-genome projects, such as the rice-genome sequencing initiative, plant proteomics is now set to explode on a global scale. With increased development of high-throughput proteome technologies, and the availability of completely sequenced plant genomes on publicly accessible databases, there is now a real opportunity for plant scientists and agricultural biotechnology companies to contribute to, and capitalize on these developments for discovery.

PSEUDOCEREALS, OVERVIEW

R J Fletcher, University of Queensland, Gatton, QLD, Australia

Introduction

Most human foods come from plants. Roots, underground storage or propagation organs, stems, petioles, shoots, flowers, or fruits are eaten. Fruits in the form of grains or seeds are the major form of human food.

Almost all of the grains eaten by humans are cereals. A cereal grain contains an embryo and usually a quantity of endosperm, enclosed within a seedcoat. Cereals are one type of monocotyledonous plant (all of which present a single shoot on germination); pseudocereals are noncereals, comprising noncereal monocotyledonous plants as well as dicotyledonous plants; the latter have grains containing no endosperm but an embryo enclosing perisperm.

The usefulness of any grain as human food (its functionality) depends on the quantity and quality of protein, starch, and lipid (fats and oils) present in the tissues of the grain (embryo, endosperm and/or seedcoat).

Grain functionality depends principally on the genetic and environmental influences on protein, starch, and lipid.

The proportion of embryo, endosperm, or perisperm within any grain is primarily determined by a plant's genetic make-up. The eventual composition of the grain can be influenced by the natural growing conditions and the manner in which the crop and its product have been managed. Important environmental factors not only include the growing conditions but also the method of harvesting, the manner in which the grain was stored, the nature of any processing carried out, including the extraction method used, and the presence of any antinutritional factors.

Grains used in the human diet come from surprisingly few crops.

Such crops are collectively referred to as the cereals (including crops such as wheat, rice, maize, barley, oats, rye, etc.), pulses (including bean, chickpea, cowpea, pigeonpea, lentil, lupine, etc.), oilseeds (including canola, sunflower, safflower, sesame, coconut, cottonseed, flaxseed, mustard, etc., as well as some pulse crops, such as soybean and peanut) or pseudocereals.

There can be some confusion with the use of such crop groupings, since each grouping is not mutually exclusive; for example, some pulse crops are used as oilseed crops and the term pseudocereal is sometimes used to refer to crops more commonly identified as oilseeds or legumes.

Definition

The American Heritage Dictionary of the English language defines a pseudocereal as "any of several plants,

such as quinoa, that do not belong to the grass family but produce fruits and seeds used as flour for bread and other staples."

The Oxford English Dictionary defines the term cereal as "a name given to those plants of the family Graminaceae [now Poaceae] or grasses which are cultivated for their seed as human food . . . sometimes extended to cultivated leguminous plants." The term pseudo is defined as "false, pretended, counterfeit, spurious, sham, falsely so called or represented." When combined with another element, such as the term cereal, pseudo is defined as "indicating close or deceptive resemblance to the thing denoted by the second element, without real identity or affinity with it."

The term pseudocereal is best used to refer to a plant which is grown as a crop to produce starchy grain suitable for human food, excluding plants already classified in a grouping such as the cereals (those species from the grass family Gramineae), pulses (those species from the legume families Leguminosae-Caesalpinioideae, Leguminosae-Mimosoideae, and Leguminosae-Papilionoideae), oilseeds (those species described in terms of the commercially useful lipid or tricylglycerol content), or nuts.

Current Role of Pseudocereals

The pseudocereals are relatively unimportant on a global scale today. However, they have been significant contributors to the human diet in certain defined regions in the past and could be developed again as important new crops. For example, pseudocereals may play a role in human nutrition for those who have allergies to traditional cereals; for the primary producer, pseudocereals can play a role in cereal rotations, reducing the buildup of grass weeds, pests, or diseases.

The three best-known pseudocereal crops are grain amaranth (*Amaranthus caudatus*, *A. cruentus*, *A. hypochondriacus*; family: Amaranthceae; *see* **Amaranth**), quinoa (*Chenopodium quinoa* subsp. *quinoa*; Chenopodiaceae; *see* **Quinoa**), and buckwheat (*Fagopyrum esculentum*; Polygonaceae; *see* **Buckwheat**). Each is briefly described below, from the viewpoint of functionality. A range of potential pseudocereals from other plant families is then presented, with dicotyledonous families followed by monocotyledonous families.

Weeds

Many of the species listed as potential pseudocereals below are currently regarded, in some areas, as weeds; one of them, *Amaranthus retroflexus*, could be regarded as the world's most cosmopolitan weed.

A weed is defined as a plant which is growing in the wrong place. If some of the potential pseudocereals listed below can be commercialized, they would no longer be regarded as weeds.

Warning

The historic use of any obscure plant by a culture for medicinal or similar personal use does not mean that the plant is safe for use as a human food. Poisonous or antinutritional factors exist in many plants and their historic use was often complemented by elaborate preparation to reduce the effect of any poison. As an example, Australian aborigines were able to consume cycad seeds and yams but only after extensive preparation, which reduced the toxicity of the material.

Regular use of a plant over a lifetime by a group of people may also render a plant relatively safe for that group of people, whereas a newcomer who has never eaten the food can suffer serious effects on eating it for the first time.

Amaranthaceae

***Amaranthus caudatus, A. cruentus, A. hypochondriacus* (grain amaranth)** *Amaranthus caudatus* (Inca wheat, love-lies-bleeding) is native to the northern higher-altitude regions of Bolivia, Peru, and Ecuador, whereas *Amaranthus cruentus* (Purple amaranth) and *Amaranthus hypochondriacus* (Prince's feather) are native to Guatemala and Mexico. The species were grown by pre-Colombian civilizations, Aztecs, and indigenous US tribes but have mostly been replaced by cereal crops.

Depending on the species, grain amaranth seeds are sprouted, parched, toasted, ground into flour, baked, mixed with sugar to make confectionery items, rolled into balls, cooked as porridge or popped.

Grain amaranth has enjoyed a resurgence in recent years, especially through the health food market, since its crude protein is high (14–19%), with a high lysine (up to perhaps 6% of the protein) and tryptophan content. It appeals to the modern consumer since these essential amino acids are low in cereals.

Grain amaranth is being developed as an energy food to be combined with traditional cereal grains in breakfast food, bread, multigrain crackers, pastes, pancake mixes, or popped as a snack food product. Popping can, however, affect its nutritional quality.

The grain is easy to digest and heat processing improves its digestibility.

Amaranth starch (up to 69% of the grain) is principally amylopectin; granules are relatively small

(1–3 μm) compared with cereals (3–30 μm) and have a higher solubility and gelatinization temperature, rendering a distinctive gel. The seed can comprise as much as 10% oil; this oil contains squalene, which is used in cosmetics manufacturing. Antinutritional trypsin inhibitors occur in concentrations up to twice that observed in wheat.

Potential pseudocereals in the Amaranthaceae family

- *Amaranthus dubius* (spleen amaranth, khada sag), *Amaranthus frumentaceous* (poong keeray, tola kura), *Amaranthus tricolor* (tampala), *Amaranthus graecizans* (spreading pigweed), *Amaranthus blitum* (livid amaranth), *Amaranthus quitensis* (yuyo colorado, sangorache), *Amaranthus retroflexus* (redroot, pigweed), *Amaranthus spinosus* (spiny amaranth): the seeds are eaten raw in India and other places or mixed with other grains or processed into flour or other products.
- *Achyranthes aspera* (devil's horsewhip, prickly chaff-flower): the seeds have been used in desert areas in India as a famine food.
- *Celosia argentea* var. *argentea* (red-fox), *Celosia argentea* var. *cristata* (cockscomb): the seeds of these species have been used as famine foods.

Chenopodiaceae

Chenopodium quinoa* subsp. *quinoa* (quinoa)Chenopodium quinoa* subsp. *quinoa* is native to the border areas between Peru and Bolivia. It held a special position in the agricultural and ceremonial life of the Inca people and was grown in Colombia, Peru, the southern areas of Bolivia, the northern areas of Argentina, and the central areas of Chile.

Quinoa grain has a protein content ranging as high as 22.8%, a carbohydrate content up to 77.4%, a fat content up to 9.5% (and relatively stable), and a fiber content up to 5.8%. The grain is higher in protein, fat and fiber, and lower in carbohydrate content than most comparable cereals, due principally to the proportional size of the embryo within the grain (up to 30% of the grain's gross weight, compared with 1% for most cereals).

The proteins in quinoa are principally albumins and globulins, which are at higher concentrations than is normally found in the major cereals (wheat, rice, or maize). The amino acid balance (higher in histidine, lysine, isoleucine, methionine, and cysteine content) and mineral content (calcium, magnesium, phosphorus, potassium, and iron) of quinoa grain is superior to most cereals. However, there are saponins in the seedcoat which have antinutritional properties.

Potential pseudocereals in the Chenopodiaceae family

- *Chenopodium album (fat hen, lamb's quarters)*. The seed is sprouted or ground into flour for breads, pancakes, muffins, and biscuits in Russia and China; the grain is reported to have 16.1% protein, 6.9% fat, 48.9% carbohydrate, and 5.8% ash.
- *Chenopodium ambrosioides (wormseed, Mexican tea)*. In the Himalayas, the seed is ground into flour and mixed with warm water or roasted or added to alcoholic beverages; care needs to be taken with its preparation and use.
- *Chenopodium berlandieri* subsp. *nuttalliae (southern huauzontle)*. The seed is ground to a meal and used for bread or gruel (a light form of porridge produced by boiling meal in water or milk).
- *Chenopodium murale (nettle-leaf goosefoot, sowbane)*. The seed is popped or parched and ground to make gruel.
- *Chenopodium pallidicaule (canihua)*. The seed is toasted and ground into a flour and eaten as a breakfast food, mixed with wheat flour in baked products or drunk as a beverage.
- *Chenopodium* sp. *(California Yokuts lamb's quarters)*. This selection was used as a semi-domesticated grain crop by Yokuts Indian villages, in the Central Valley, California.
- *Atriplex canescens (fourwing saltbush)*. The seed is ground into meal and used as flour, or as a beverage.
- *Atriplex confertifolia (shadscale)*. The seed is ground into meal and used for bread or mush (a heavier form of porridge than gruel, produced by boiling meal in water or milk).
- *Atriplex hortensis (orache)*. Flour is prepared from the seeds and used in soup and muffins; the seed is reportedly rich in vitamin A.
- *Atriplex lentiformis (quail bush) and Atriplex polycarpa (all scale)*. The seeds are eaten by the Native American Pima group, located in Arizona.
- *Atriplex patula (halberd-leaved saltbush)*. The seed is ground and mixed with corn and steamed as meat balls by the Zuni Indians.
- *Atriplex prostrata* (hastate saltplant). The seed is ground into flour for use in baked products.
- *Haloxylon sadicornicum*. The seeds are mixed with other grains for bread making in India.
- *Suaeda corniculata and Suaeda heteroptera*. The seeds are eaten raw in Manchuria.
- *Tecticornia verrucosa*. The seeds are ground to flour by Australian aborigines and baked.

Polygonaceae

Fagopyrum esculentum **(buckwheat)** Buckwheat originated from south central China.

This crop is harvested with its green pericarp intact; once the pericarp (hull) has been removed, the groat can be coarsely milled into grits for breakfast food or roasted and sold in whole or a granulated form to be boiled, steamed, or baked. Buckwheat flour itself is used in soba-style Japanese noodles, polenta (a form of porridge), desserts, ice cream cones, dietetic foods, and canned meat or vegetable products and as a component (30–40%) of the flour used in pancakes, breads, pasta products, cakes and dumplings, often combined with wheat flour.

It is expected that buckwheat flour could be used more readily in specialty breads, pasta, extruded snack food, and ready-to-eat cereals.

The proteins in buckwheat grain are principally globulins with a small proportion of prolamins; buckwheat protein has twice the lysine content of wheat or white rice. The grains are relatively high in potassium, magnesium, phosphate, iron, and vitamins B_1 and B_2.

Potential pseudocereals in the Polygonaceae family

- *Fagopyrum cymosum (perennial buckwheat) or Fagopyrum tataricum (Tartary buckwheat).* In the Himalayas, the seeds are eaten or ground into flour.
- *Calligonum polygonoides (phog, phogalli).* The seeds are eaten raw in India.
- *Polygonum aviculare (knotgrass, gooseweed).* The seeds are eaten or ground into flour for use in cookies or pancakes; they are sometimes mixed with wheat; care needs to be taken with their preparation and eating.
- *Polygonum glabrum (sauri arak, jioti, aatlaria).* The seeds are parched and made into a kind of Indian “sattu” (a traditional weaning food mix often eaten by adults, usually based upon roasted Bengal gram, wheat, and sugar with spices added and served in a number of ways, including as a porridge).
- *Polygonum orientale* (Prince’s feather). The seeds are eaten in China.
- *Polygonum plebeium (chimtee sag, raniphul, machichi).* The seeds are crushed on stones, cooked, and eaten in the form of a damper; the dry seed contains 17.4% protein, 50.4% carbohydrate, 3% fat, and 16.2% fiber.
- *Rumex acetosa (sorrel dock).* The seeds are used as a base for bread in Scandinavian countries; care needs to be taken with their preparation and eating.
- *Rumex acetosella* subsp. *acetosella (sheep sorrel).* The seeds are ground into flour to make a flat bread called sygrasbrod.
- *Rumex crispus (curled dock).* The seeds are ground into meal or flour and used in pancakes; care needs to be taken with preparation and eating.

Potential Pseudocereals in Other Dicot Families

Other dicotyledonous families with potential pseudocereal species producing starchy grains include: Bixaceae, Cactaceae, Cannabidaceae, Caryophyllaceae, Chloranthaceae, Cistaceae, Portulacaceae, and Trapaceae. Species of potential interest are named in the following.

There are many other minor dicotyledonous families with plants producing starchy grains which will not be referred to again; these include: Ancistrocladaceae, Basellaceae, Buddlejaceae, Desfontainiaceae, Dioncophyllaceae, Droseraceae, Erythroxylaceae, Frankeniaceae, Gelsemiaceae, Leitneriaceae, Lennoaceae, Molluginaceae, Nepenthaceae, Nyctaginaceae, Orobanchaeae, Pentaphragmataceae, Phytolaccaceae, Retziaceae, Sarcolaenaceae, Sargentodoxaceae, Saururaceae, Schisandraceae, Stegnospermataceae, and Tamaricaceae. Most of these families have very limited numbers of species.

Bixaceae

Bixa orellana (annatto). The seeds are used as coloring and flavoring for meat, poultry, or fish; the seedcoat contains the carotenoid, bixin, which is used as a tasteless coloring for cheese, butter, margarine and chocolate and for color in soap and skin products.

Cactaceae

- *Carnegiea gigantea (giant cactus).* The seeds are ground into flour and used to make soup, paste, and other products by the Native American Papago group.
- *Ferocactus wislizeni (fishhook cactus).* The seeds are ground, parched, and used for bread and gruel.
- *Opuntia clavata (ishikana).* The seeds are roasted by Native Americans of the Acoma and Laguna groups; however, the mucilage in the fruit can render the food objectionable.
- *Opuntia phaeacantha (bastard fig).* The seeds are dried, parched, and ground into meal for gruel and cakes.
- *Opuntia soehrensii (ayrampo).* A violet dye is extracted from the seeds and used as a food coloring.

- *Pachycereus pecten-aboriginum (cardon hecho hecho)*. In Mexico, the seeds are ground and made into cakes.
- *Pachycereus pringlei (cardon)*. The seeds are toasted, ground, and fashioned into balls.
- *Stenocereus stellatus (xoconochtli, joconostle)*. The seeds have been eaten.

Cannabidaceae

Cannabis sativa (hemp). The seeds are parched, fried as cakes, used in asanomi (in Japan), in the spice mix shichimi, in ale or are eaten as sprouts.

Caryophyllaceae

- *Lychnia segetum*. The seeds have been eaten as a famine food in France.
- *Spergularia arvensis (corn spurrey)*. The seeds are used for bread flour in Norway and Sweden.
- *Stellaria media (chickweed)*. The seeds are used as bread or as a soup thickening in India.

Chloranthaceae

Sarcandra glabra (tea scent). The seeds are roasted and used as a sesame substitute.

Cistaceae

Cistus ladanifer (labdanum). The seeds are ground and used for cakes and breads.

Portulacaceae

Portulaca oleracea (purslane). The seeds are sprouted or ground for use in gruel, cake, bread, or pancakes; the content of glycine and tyrosine in the seeds is reportedly high; care needs to be taken with their preparation and eating.

Trapaceae

- *Trapa natans (water caltrop, water truffle)*. The seeds are eaten raw, roasted, boiled, fried, or ground into flour for bread and sweet puddings.
- *Trapa bispinosa*. The seeds are cooked and eaten in India.

Potential Pseudocereals in Monocot Families

Monocotyledonous families with potential pseudocereal species include: Araceae, Cannaceae, Commelinaceae, Cyperaceae, Marantaceae, Musaceae, Palmae, Pandanaceae, Pontederiaceae, Typhaceae, and Zingiberaceae. Species of potential interest are named in the following.

There are also many minor monocotyledonous families with plants that produce starchy grains which will not be referred to again; these include: Alismataceae, Anarthriaceae, Aponogetonaceae, Bromeliaceae, Burmanniaceae, Butomaceae, Centrolepidaceae, Costaceae, Cyanastraceae, Cyclanthaceae, Eriocaulaceae, Flagellariaceae, Haemodoraceae, Hydatellaceae, Hydrocharitaceae, Joinvilleaceae, Juncaceae, Juncaginaceae, Lemnaceae, Mayacaceae, Melanthiaceae, Najadaceae, Philydraceae, Potamogetonaceae, Rapateaceae, Rhipogonaceae, Scheuchzeriaceae, Sparganiaceae, Triuridaceae, and Velloziaceae.

Araceae

Peltandra virginica (arrow arum, tuckahoe). The seed produces a bread similar to corn bread, with a cocoa flavor.

Cannaceae

Canna edulis (Queensland arrowroot). Immature seeds are cooked in tortillas or cakes; the plant is used as a source of arrowroot in Colombia.

Commelinaceae

- *Commelina benghalensis (keng, bokna, mu-Kengeria), Commelina forskailii (kansura, kanshura)*. The seeds are ground into flour for bread.
- *Commelina communis (spider wort, day flower), Commelina obliqua (kena, keni, kana, kanjura)*. The seeds are eaten.
- *Cyanotis axilaris (vichaka, narido, damro, soltra)*. The seeds are ground into flour for bread or bhadku, a mixture of flour and salt.

Cyperaceae

- *Cyperus bulbosus (theg, motha, mothabasa)*. The seed is ground into flour and made into bread or “ghes” or “rab” in India; Australian aborigines ate the seed raw or roasted.
- *Mariscus sieberianus (tall sedge)*. The seeds are made into flour in China.
- *Scirpus lacustris (great bulrush)*. The seeds are ground and mixed with meal for bread, mush, or pancakes.
- *Scirpus maritimus (chid, dila)*. The seeds are eaten raw or pounded, made into flour and mixed with millet in India.
- *Scirpus validus (tall bulrush)*. The seeds are eaten.

Marantaceae

Thaumatococcus danielli (miracle berry). The seeds are used as a sweetener but the extract does not withstand heat.

Musaceae

Ensete ventricosum (Abyssinian banana). The endosperm of the seed is eaten in Africa.

Palmae/Arecaceae

Hyphaene thebaica (gingerbread palm). The kernels are crushed and mixed with porridge; the edible portion of the kernel has 2.8% protein, 74.7% carbohydrate, 0.4% fat, and 11% crude fiber.

Pandanaceae

Pandanus tectorius (Nicobar breadfruit, screwpine). The seeds are edible but only after careful preparation.

Pontederiaceae

Pontederia cordata var. *cordata* (lance-leaf pickerel weed). The seeds are eaten raw, boiled or parched, and ground into flour for bread.

Typhaceae

Typha angustifolia (narrow-leaf cattail). The seeds are roasted and eaten.

Zingiberaceae

- *Aframomum angustifolium (Madagascar cardamom)*. The dried seeds are used like pepper or added to coffee.
- *Aframomum melegueta (Melegueta pepper)*. The seeds are used as flavoring for beverages, meats, ice cream, candy, and bread.
- *Amomum compactum (round cardamom)*. The seeds are used in cakes in Malaysia.
- *Amomum subulatum (Indian cardamom)*. The seeds are used for flavoring in char masala, in Afghanistan.
- *Amomum xanthioides (bastard cardamom)*. The seeds are used as flavoring in liqueurs in China.
- *Elettaria cardamomum (cardamom)*. The seeds are used as flavoring.
- *Etlingera elatior (Phillipine wax-flower, ondje)*. The seeds are eaten raw in Malaysia.

Conclusion

In the past, the pseudocereals have represented an important component of the diet of many people in a wide range of cultures. The representative list of potential pseudocereals included above demonstrates the opportunities for future development of functional foods that exist amongst the pseudocereals, based on the usefulness of these foods in the past. In addition, the reputation of so many of the species as weeds indicates that they will probably have growth characteristics which should assist with their development into modern commercial production systems.

PULSES, OVERVIEW

T E Michaels, University of Minnesota, St. Paul, MN, USA

Introduction

> Then said Daniel to Melzar, whom the prince of the eunuchs had set over Daniel, Hananiah, Mishael, and Azariah, prove thy servants, I beseech thee, ten days; and let them give us pulse to eat, and water to drink. Then let our countenances be looked upon before thee, and the countenance of the children that eat of the portion of the king's meat: and as thou seest, deal with thy servants.
>
> Daniel 1 : 11–13 (RSV)

Grain legumes are plants belonging to the legume family (*Leguminosae*) that produce seeds used directly for human food. Humans particularly value this group of plants for the protein contributed by their seeds to our diets. Grain legumes are commonly subdivided into pulses, which, in addition to protein, store high levels of carbohydrate (>60%) and low amounts of lipid (<6%) in their dry seeds, and leguminous oilseeds which boast higher lipid, but lower carbohydrate levels than pulses (Tables 1 and 2). In this organizational structure, soybean (*Glycine max*) and peanut (groundnut, *Arachis hypogaea*) are typically categorized as oilseeds while common beans (*Phaseolus vulgaris*) and cowpea (*Vigna unguiculata*) are considered pulses. Pulses also contain high levels of dietary fiber (~20 g fiber per 100 g compared to 12 g fiber per 100 g for wheat, 9 g fiber per 100 g for soybean, and 3 g fiber per 100 g for rice).

Pulses are ancient foods that help fulfill the ageless need to sustain body and soul, as exemplified by Daniel's insistence on a simple plant-based diet over the meat-rich diet provided by King Nebuchadnezzar. The word "pulse" arrived in modern English from the Greek "poltos" meaning "porridge of meal," by way of Latin ("puls," "pultis"), Old French ("pols"), and Middle English ("puls").

Gathering plant parts for food is a reliable way (in comparison to episodic hunts for animal prey) of feeding oneself in a hunting and gathering society. Gathering pulse seeds is particularly convenient compared to parts of other plants. Pods from grain legume plants are handy and easily grabbed compared to subterranean roots and tubers. No tools other than fingers and palms are needed to grab and hang on to the large seeds. Keeping both feet firmly on the ground is less daunting than climbing trees for aerial fruits

Table 1 Names and regions of greatest genetic diversity for major pulse species

Botanical name	*Common and vernacular names*	*Center of domestication*
Cajanus cajan	Pigeon pea, angola pea, congo pea, dhal, no-eye pea, red gram	India
Cicer arietinum	Chickpea, garbanzo bean, gram	Southeast Turkey
Macrotyloma uniflorum	Horse gram	
Lathyrus sativus	Grasspea, chickling vetch	Southern Europe, Southwest Asia
Lens culinaris	Lentil, split pea, red dhal, masur, lenteja, lentille, manssor, burssum	Eastern Mediterranean, Fertile Crescent (Iraq, Iran)
Phaseolus vulgaris	Common bean, dry bean, kidney bean, frijol, caraota, poroto, habichuela, haricot bean, snap bean	Mexico and Peru
Phaseolus lunatus	Lima bean	Peru, Central America, Caribbean
Pisum sativum	Field pea, garden pea, Guisante, muttar, pois, arveja, Alaska pea	Fertile Crescent (Iraq, Iran), Turkey, Greece
Vicia faba	Broad bean, faba bean, horse bean, Windsor bean, haba, feve	Eastern Mediterranean, West Asia
Vigna radiata	Green gram, golden gram, mung bean, oregon pea, chickasano pea	India, Southeast Asia
Vigna mungo	Mung bean, black gram, urd, kambulu, uride	India
Vigna unguiculata	Cowpea, catjang, Hindu cowpea, kaffir bean, black-eyed pea, frijol, caupi	Sub-Saharan Africa

and nuts. The dense seeds are more filling than leaves, and will satisfy hunger in the absence of meat if hunting is unsuccessful. As a bonus to those concerned about times of scarcity, the seeds can be dried and stored for a period of months or more without loss of food value when eaten, or viability when planted. Pulse seeds are large relative to cereals, so they are convenient to handle for food preparation and planting. Because of their convenience, availability, and composition, wild pulses were an accessible, nutritional contributor to early hunting and gathering societies across the world.

The wild progenitors from which pulses were domesticated have been identified, with the exception of *Vicia faba*. The archeological record for some pulses, particularly *Phaseolus* species and *Lens culinaris*, is more complete than for others such as *Vigna unguiculata* and *Cajanus cajan*. In whatever manner they were developed, the domesticates quickly spread across regions and continents, particularly to regions lacking a wide range of highly desirable, locally domesticated food crops such as Europe and North America. Over time, domestication, selection, and trade resulted in a wide variety of pulses grown, contributing protein to human diets across the globe. Pulse and cereal grain domestication appear to have taken place at roughly the same time in human history, which suggests that these two foods may be ancient partners in providing human nutrition. While cereals provided most of the energy and much of the protein requirements of humans, pulses played a strong supporting role as a contributor of concentrated dietary protein. Concurrent pulse and cereal production and their dietary consumption resulted in more sustainable farming systems, as well as better nutritional balance, than would have been derived from production and consumption of cereals alone.

Table 2 Protein and other nutritional constituents of pulses and other reference foods (g constituent 100 g food^{-1})

Food	*Protein*	*Lipid*	*Carbohydrate*	*Water*
Pulses				
Common bean	22.2	1.1	61.5	11.5
Lima bean	21.5	0.7	63.4	10.7
Chickpea	19.3	6.0	60.7	11.5
Green gram	23.9	1.1	62.6	9.0
Cowpea	23.8	2.1	59.6	11.1
Oilseed legumes				
Soybean	36.5	19.9	30.2	8.5
Peanut	25.8	49.2	16.1	6.5
Cereals				
Wheat, hard white	11.3	1.7	75.9	9.6
Brown rice, raw	7.5	2.7	76.2	12.4
Animal products				
Beef, lean ground	20.0	10.0	0.0	69.5
Pork, ground	16.9	21.2	0.0	61.0
Fish, cod	17.8	0.7	0.0	81.2
Milk, cow's 3.25% fat	3.3	3.3	4.7	88.0
Egg, hen's	12.5	10.0	1.2	75.3

Consumption

Current pulse consumption in many parts of the Old and New World appears to be affected by cultural inertia; past consumption patterns in those regions are echoed in the present. While pulses are common components of diets around the world, the extent to which they contribute to the diet correlates closely with the historic availability and acceptance of animal protein. Ancient civilizations that consumed more pulses were those where animal protein was less available or acceptable. They included those that maintained high human population densities and overwhelmed local supplies of wild and domestic animal protein (East Asian Old World civilizations), those where few animals were domesticated (Aztec and Mayan New World civilizations), and those where predominant religious practices excluded animal protein consumption (Hindu veneration of the cow in South Central Asia). Even today, those regions of the world consume more pulses than elsewhere.

Besides influencing the amount of pulse contribution to the diet, cultural inertia expresses a parallel effect on the pulse species consumed within a region. Those pulses with long records of use in a particular country or region of the world continue as dietary preferences today (Table 3).

The 40 day fast of Jesus in the desert became the standard reference early in the Common Era for the custom of mortification of the body by monks belonging to the Roman Church. The fasting monks had to be engaged in conducting monastery's daily functions; thus, the elders of the monastic community began, in the fourth century, to standardize the fast diet, in order to ensure that their workforce received at least the nutrition required to keep body and soul intact, but without arousing earthly sensuality in monks eating flavorful food. A satisfyingly dull puree of pulses, accompanied perhaps by a vegetable soup, became typical of the single meal allowed during fasts. Monks certainly had their fill of pulses as they contemplated eternity; the fifth century monasteries scheduled ~230 fast days per year.

Before widespread adoption in seventeenth century, Europe of cuisine innovations such as leavened bread and three-a-day meals, people of medieval

societies typically ate warm servings of porridge twice daily. These plates or bowls of boiled gruel incorporated readily available and affordable cereal grains such as barley and wheat, and also pulses such as the wild-growing or domesticated lentils first found in the Eastern Mediterranean and West Asia. Meat consumption declined with increasing population, decline of wild gamestocks, and movement of people into towns and cities. World trade, natural sciences, and the influence of aristocratic culture began to influence diets in the late 1600s. Three-a-day meals became common across socio-economic groups and cookbooks spread food culture throughout the urban and rural society. New foods – including spices, potatoes, and a thickener made by browning flour in fat known as *roux* – made their appearance and elbowed the cereal-and-pulse porridge out of popularity. The reformation de-emphasized fasting which further reduced the consumption of sturdy pulse porridges.

Composition

Pulses, with roughly double the protein content of cereals, are damned with faint praise as the protein of the poor. They contribute excellent nutrition to all, but because they are inexpensive relative to meat, they are particularly beneficial to subsistence farmers and those with low disposable income in food-deficient countries. In such circumstances, pulses can account for ~10% of daily protein intake and 5% of the daily energy in the human diet (Table 4). The praise, however, is faint and damning because this association with poverty, a connection perhaps firmly established with the porridges of the Middle Ages, stigmatizes pulse foods among those with or aspiring to higher income who increasingly favor meat protein. Scarcely, 2% of dietary protein in developed countries comes from pulses. In more affluent settings, pulses remain an underused alternative to high-priced animal protein. Interestingly, at least one segment of affluent society, lifestyle- or health-conscious eaters such as vegetarians or those seeking the nutritional benefits of high dietary fiber, still treasures these plants. Pulse consumption is declining on a per capita basis, regardless of economic status. The increased protein consumption recorded in developing countries is due to inclusion of additional cereals, meat, and milk in the diet. One aggravating reason for low consumption is flatulence, a well-known side effect of pulse consumption, and intestinal fermentation of complex sugars and dietary fiber. If gassiness causes the consumer discomfort or embarrassment, pulse foods will be avoided when other choices are available.

Based on data from Anonymous (2002) *Dietary Reference Intakes for Energy, Carbohydrates, Fiber, Fat, Protein and Amino Acids (Macronutrients)*. Chap. 10, p. 71. Washington, DC: National Academies Press (Online version available on p. 535 at the URL http://www.nap.edu/books/0309085373/html/).

Developed countries are currently net exporters of pulses, while developing and low income countries are net importers (Table 5). Trade in pulses has grown substantially since the 1960s. During that period the rate of growth in pulse imports was greatest in the poorest countries, and export growth was the greatest in the most affluent. The poorest countries also had the greatest rate of growth in pulse utilization for livestock feed.

Protein Complementation

Understanding amino acid balance is key to recognizing the special contribution made by pulses to protein complementation in cereal-based diets. Different sources of plant protein are made up of characteristic concentrations of indispensable (essential) amino acids, and therefore contribute upon digestion a different balance of amino acids for human nutrition. Amino acid balance in a particular protein source can be scored against that of a reference protein, typically hen's egg (regarded as well balanced in relation to adult human metabolic needs) or milk (Table 6). No plant-based protein mimics the indispensable amino acid balance present in egg, so it follows that each type of plant protein must exhibit a characteristic set of limiting amino acids. Whole wheat flour and white-seeded common beans generally have lower proportions of the indispensable amino acids than do egg or milk. In particular, the amino acid lysine limits efficient utilization of wheat protein in human metabolism, while the indispensable sulfur-containing amino acid methionine limits bean protein. The indispensable amino acid balance of wheat and bean is characteristic of other cereal grains and pulses. Cereal grains are typically deficient in lysine, but high in methionine, while the opposite is the case for pulses: high in lysine, low in methionine. Cysteine, a dispensable sulfur-containing amino acid synthesized from methionine and serine, is in many references listed along with methionine as a limiting amino acid of pulses.

Plant protein complementation, accomplished by consuming protein from more than one plant source, can provide humans with a balanced diet of amino acids. Pulses, with their high concentration of lysine relative to lysine-deficient cereals, and cereals, with their high concentration of methionine and cysteine relative to that found in pulses, dance as ideal dietary partners, because the amino acids making up their proteins are very good complements. For example, at 0.7 g per kg body mass day^{-1}, an 85 kg adult would require ~60 g of protein per day containing at least 2820 mg lysine. This requirement could be

satisfied by consumption of 288 g wheat (*Tricicum aestivum*) and 124 g bean (*Phaseolus vulgaris*) (Tables 2 and 6). To meet the lysine requirement through consumption of wheat alone, the same adult would need to eat 960 g wheat containing ~108 g total protein. The intentional combination of cereals and pulses at meals offers inexpensive (in comparison to meat) plant-based diets with balanced amino acid composition.

While the central theme of this overview is the enormous contribution made by dry pulse seeds to the human diet, pulses have other food uses. Some species are used as vegetables either as green mature or immature seeds or pods, as sprouted seeds, or even as stocks for fermentation. Fermented pulses – primarily involving black gram (*Vigna mungo*), Bengal gram (*Cicer arietinum*), and green gram (*Vigna radiata*) – are components of diets particularly in India as "idli," "dhokla," and "khaman." Fermentation, sometimes in combination with cereal grains, causes desirable reduction in beany flavor, aroma, and consistency, and improves digestibility.

Nonfood uses include dry seeds used as animal feed, forage from pulse vegetation, in aquaculture feeds, and even as ornamentals. In a Southeast Asian setting, well-established shrubs of pigeon pea, a short-term perennial grown on field banks or as an intercrop, as well as dry-season grown horse gram and cowpea, can be intermittently grazed or cut for hay. N concentration of the hay varies between 2.5% and 4.5%, but livestock may need a few days to be accustomed to the feed. Dairy cattle are reported to similarly consume and utilize faba bean silage and grass-legume silage. From a cool-season perspective, seeds of pea, lentil, faba bean, and chickpea can be used as a protein source in livestock feed. Oil and fiber contents of the seeds affect the metabolizable energy values (MEn) of pulses when fed to various types of livestock. For example, the relatively low-oil, high-fiber pea has a low (2570 kcal kg^{-1}) MEn when fed to poultry, while for swine the pea MEn is much higher (3740 kcal kg^{-1}). Pulse seed amino acid profile for monogastric feeds, while good, is inferior to soybean. Pea and faba bean protein is highly digested, but some livestock feeding studies have shown an increased excretion of endogenous protein, which may be due to seed antinutrients. Dry-roasting the whole seeds has been shown to improve digestibility and protein utilization. Pulses have great potential for use in aquaculture diets, but in this application are hampered by their carbohydrates. However, field peas (*Pisum sativum*), faba beans (*Vicia faba*), chickpeas (*Cicer arietinum*), and vetch (*Vicia sativa*) seeds can be used in aquaculture feeds for juvenile silver perch following de-hulling, which removes much of the undesirable carbohydrate fraction.

Antinutritional Factors

Low digestibility hampers full utilization of pulse protein. In part, the problem may result from the more rapid discharge, relative to other foods, of digesting pulses from the intestinal tract and reduced protein hydrolysis by gut enzymes. However, antinutritional factors, compounds in pulses that interfere with their digestion and metabolism, also play a major role in restricting dietary utilization in some pulse species. These compounds generally include proteinaceous molecules such as protease inhibitors (particularly trypsin inhibitors), and lectins, and also nonproteinaceous compounds such as tannins.

Most of the wild relatives of pulses contain toxins and antimetabolites. One of the key features of pulse domestication from wild forms is human selection for lower levels of these compounds. Traditional food-preparation techniques used for pulse seeds result in reduction or elimination of these metabolic impediments. Some modern food pulses today, in particular the *Phaseolus* species, can still contain sufficiently high levels of antinutritional factors in their dry seeds to cause digestive difficulties if eaten without proper processing. For this reason, pulse seeds are not eaten raw, but processed in a way (moist heat >100°C, sprouting, fermentation) that inactivates the antinutritional factors.

Protease inhibitors, a major class of antinutritional factors in pulses, often inhibit the digestive enzyme trypsin, but may act more broadly by inhibiting chymotrypsin and other serine proteases. The role of these inhibitors in the plants that produce them is uncertain, but may involve defense against disease and insects. An alternative explanation is that these compounds might simply serve as protein reserves high in sulfur-containing amino acids such as cysteine and coincidentally inhibit human digestion. The primary concern regarding raw pulse consumption is with very young humans and other young animals that are more susceptible to the effects of protease inhibitors than adults. *In vitro* studies suggest that protease inhibitors can impair nutrient utilization and reduce growth rates in these groups. *In vivo* animal studies indicate that interference with growth occurs primarily when the level of dietary protein itself is limiting. Pancreas activity can be affected when dietary protein digestion is inhibited and high levels of undigested protein interfere with appropriate pancreatic regulatory control. Since pulses are used in some human infant diets, cooking must be done with

particular care to ensure that protease inhibitors are inactivated.

Lectins, another major class of antinutritional factors in pulses, are proteins that bind to carbohydrates or to molecules containing carbohydrates. This binding capacity allows them to agglutinate red blood cells (lectins are sometimes called phytohemaglutinins) of different animal species depending on the specific receptors on the cell membrane surface. This agglutination specificity provides a method of rapid detection and classification. Lectins differ in the severity of their impact. Some (mainly found in *Phaseolus vulgaris*) are classified as toxic, others are considered only growth inhibitory (*P. lunatus*) and still others essentially nontoxic (*Pisum sativum, Lens culinaris, Vicia faba*). The role of lectins in the plant is not well established, although they appear to help the plant defend itself against specific bacteria, fungi, and insects. They may also aid processing and movements of glycosylated storage materials during seed maturation, assist in establishment of the symbiotic relationship of legumes and rhizobia, and promote cell growth and division. Or, like protease inhibitors, lectins may simply serve as storage proteins.

The effect of ingested lectins on human and other animal metabolism varies according to the lectin type, the species ingesting the protein, and the age, nutritional, and health status of that human or animal. To affect human metabolism, plant lectins first must bind to epithelial cells in the gut. This binding requires the presence of particular carbohydrate groups on the lumen of the gut epithelial cells. Dietary lectins strongly resist proteolytic degradation in the gut. Toxic dietary lectins can modify hormone balance, lipid, and muscle metabolism. These modifications deplete stores of lipid, glycogen, and protein and lead to weight loss. Some nontoxic lectins bind to the gut epithelium, but have no deleterious effect on metabolism, while others exhibit only limited binding capacity. Deleterious lectin effects appear to be reversible.

Tannins can form strong cross-linked complexes with dietary proteins and enzymes. The antinutritional impact of tannins on digestion and metabolism is not fully understood.

Protease inhibitors and lectins are heat labile and rendered innocuous by usual methods of cooking. Moist heat treatment – such as the traditional soaking of beans followed by cooking in boiling water – is generally considered to be sufficient to inactivate protease inhibitors. Soaking may help leach out some tannins, but heat treatment will not reduce the impact of that remaining in the seeds.

Particular pulse species accumulate additional classes of antinutrients. For example, *Lupinus albus* seeds may contain alkaloids. Neuro- and osteo-lathyrism, the former a reversible paralysis and the latter a skeletal abnormality, have been linked to excessive consumption of grasspea (*Lathyrus sativus*) seed. Broadbean (*Vicia faba*) antinutrient levels are low and do not require moist heating or fermentation to inactivate, but can induce favism, a hemolytic anemia, in individuals with congenital deficiency of glucose-6-phosphate dehydrogenase. Pulses of Mediterranean origin – such as peas (*Pisum sativum*), chickpeas (*Cicer arietinum*), and lentils (*Lens culinaris*), generally have low toxic and antinutrient levels. While protease inhibitors have been found in cowpeas (*Vigna unguiculata*), they are apparently not present in serious levels, nor have harmful quantities of cowpea lectins been reported. *V. mungo* and *V. radiata* seeds likewise contain little in the way of antinutritional factors.

Agronomy

The Leguminosae family is enormous, with an estimated 16 000–19 000 species in ~750 genera. If the raw number of species were to determine the greatness of a family, Leguminosae would be eclipsed only by the Orchidaceae and Compositae. If instead the economic value of a family were considered, legumes would be second only to the Graminae. Taxonomists place pulses in the legume subfamily Papilionoideae, mostly in tribe Phaseoleae, but a few in the tribes Vicieae, Cicereae, and Genisteae.

Cropping systems develop in response to the demand for particular crops, soil nutrient status, soil physical structure, and biotic competition and are constrained by available resources (including climate) and knowledge. Pulses in temperate cropping systems are commonly planted in monocultures as part of a rotational sequence with maize (*Zea mays*), small grain cereals, or occasionally forages or periods of fallow in dryland areas. Since in these cropping systems pulses are typically cash crops and occasionally feed crops, their inclusion in the rotation and total acreage from year to year depends on the status of cash markets and economic benefits of growing that pulse crop relative to other crops rather than with maintaining a set crop rotation, maintaining particular soil characteristics or addressing biotic competition. Higher-value crop alternatives may be readily substituted for pulses in the rotation in some climates. National farm strategies with strong economic impact, such as government subsidies or deficiency payments, can affect pulse production by inclusion in or exclusion of particular pulse crops from the programs. For example, the United States Food Security and Rural Investment (FSRI) Act, governing USA

farm legislation for the period 2002–07, includes as program crops – dry peas, lentils, and small chickpeas – for the first time, but common beans are not included. While not a big producer of any of these pulse crops, the USA is an exporter, and additional production stimulated by the FSRI could affect prices in other pulse exporting or importing countries.

Leguminosae will collaborate with genus *Rhizobium* bacteria in an ecologically unique symbiotic relationship. This symbiosis supports biological nitrogen fixation and frees legumes from the need to access soil sources of fixed nitrogen. Rhizobia invade the legume root hairs and reside in cortical root swellings (nodules) where nitrogen from the atmosphere is fixed for eventual transport within the plant and assimilation into protein. Even though a legume can support the symbiotic relationship, it will not occur unless the rhizosphere contains compatible rhizobia. Strains of rhizobia differ according to the particular legume hosts that they will inoculate, and are classified according to this host range.

Cropping systems in developing countries typically rely on intercropping where pulses are planted along with other species, commonly cereals and vegetables. The intercropping strategy can provide subsistence farmers with several essential foods from one plot of land, produce higher protein yield per hectare, combine complementary canopy structures (low stature pulses with high stature sorghum (*Sorghum bicolor*) and maize (*Zea mays*), balance utilization of soil moisture following rainy periods, or reduce crop competition by weeds and insects. It is unlikely that a nonlegume companion crop of similar growth period will benefit directly from the pulse crop's nitrogen fixation, but perennials, crops with longer growth periods, or subsequent crops may benefit from the nutrients released through decomposition of pulse crop litter. The agronomic impact of a legume crop on the intercrop will depend on the crop species (and even the cultivar) in the intercrop, the extent of its inclusion in the plot, tillage, and soil type.

Pulses can assist in soil improvement, particularly when used as green manure crops when the whole plant is plowed down into the soil. Fixed nitrogen and in some cases phosphorus is made available to subsequent crops, and the added organic matter contributes to improved soil structure. Also, the deep tap roots of some crops such as pigeon pea reduce soil erosion and mine deep soil for nutrients that are returned to the surface through leaf drop.

In sustainable shifting cultivation systems of intercropping, a few years of crop production, are followed by a decade or more of bush fallow where cropping is suspended and native vegetation regrows. Cultivated pulses grown during the cropping years provide concentrated protein for human diets using nitrogen fixed from the atmosphere, and help maintain the soil nitrogen status by not depleting fixed soil nitrogen. During the bush fallow stage, indigenous legumes, including trees, contribute to the restoration of soil nitrogen. When human population density is low relative to available land, and bush fallow periods are sufficiently long to restore soil nutrients, shifting cultivation can be sustained. With increased population or decreased land base, the cropping period must be extended, bush fallow period reduced, and as a result soil nutrient status and crop productivity decline.

Since in most cases pulse crops are not alternate hosts for cereal crop diseases, their use in crop rotations will help reduce cereal disease innocula. However, pulses are certainly not immune to pests; they are attacked by many fungal, bacterial, and viral diseases and a range of sucking, boring, and chewing insects. Also, pulses are typically poor competitors against weeds, except perhaps under stress conditions such as drought conditions where annual weeds are also checked.

At harvest time, pulses often disappoint and frustrate growers by failing to meet yield potential. Pulses are often considered to be extremely sensitive to environmental stress, relative to the more robust cereals, a sensitivity which may in part be associated with maintaining the symbiotic relationship with *Rhizobium*. The *Rhizobium–Leguminosae* symbiosis requires energy supplied by the host plant to support the metabolic needs of the bacterial colonies in return for assimilated nitrogen. In the case of the pulses, which are typically grown as annual crops, the symbiotic relationship must be re-established with every new crop. Farmers watching the color of the growing annual pulse crops in their fields can clearly see the lag time between planting and the establishment of functioning nodules. For example, a temperate common bean crop planted in a soil with compatible rhizobia will tend to have a deeper shade of green about a month after planting, as fixed nitrogen becomes available to the plant. During the early portion of the growing season, the host plant pays the costs of establishment and only later receives the benefits. Plant-generated energy used to support the symbiotic relationship is not available to the plant for dry matter production, so some amount of yield penalty should be anticipated. Effective nodulation and nitrogen fixation depends on favorable interactions between the host and appropriate *Rhizobium* genotypes and the environment. If these interactions falter and nitrogen fixation lags behind demand, dry matter production will suffer.

Final Words

Declining per capita pulse consumption, particularly given the nutritional value of pulses and their affordability, is cause for concern. Although some regions in developed countries now benefit from new pulse export opportunities and are increasing production, this expansion reflects changing markets and increased population, not increased dietary utilization. Much more global impact could be accomplished by addressing constraints to consumption, including the social stigma associated with eating poor pulses compared to rich meat, flatulence, yield variation, and agronomic constraints to product quality and stable high yield. Reversing the decline in pulse consumption in developing and low income countries may be impossible given the strength of the human drive toward diets associated with affluence. Perhaps the greatest initial gains could occur among consumers in developed countries currently with very low pulse consumption. The keys to higher consumption in those countries may involve increasing the availability of value-added pulses such as those produced by certified organic methods or food quality assurance programs, and highlighting their inclusion in national and regional cuisine initiatives. In tandem, these efforts to add value and visibility could impart some cache to pulses and improve their appeal.

> So he consented to them in this matter, and proved them ten days. And at the end of ten days their countenances appeared fairer and fatter in flesh than all the children which did eat the portion of the king's meat. Thus Melzar took away the portion of their meat, and the wine that they should drink; and gave them pulse.

Q

QUINOA

S A Valencia-Chamorro, Escuela Politécnica Nacional, Quito, Ecuador

Introduction

Quinoa is a typical crop of the Andean region. It has been cultivated since ancient times, and was a staple food of the Inca empire. However, production of quinoa was almost completely reduced after the Spanish conquest; foreign grains were widely produced instead.

During the 1970s, initial interest in the crop increased. At the same time, higher plantation areas for cultivation of quinoa in South America and new markets for the grain in the USA and Europe were developed. Thus, quinoa is now of great interest to the scientific world, and it may become a food for the future.

The origin of quinoa and its distribution in the Andean region have been reviewed, as well as its actual distribution in North and South America and Europe. It is important to mention the strong and dedicated interest in cultivating this grain outside the borders of the former Inca empire. Classification of the grain, cultivation practices, and morphology of the plant have been described.

Quinoa has been recognized as an extremely nutritious grain all over the world, thanks to both the high quantity and good quality of its protein content as regards its essential amino acid content. Thus, an extensive review of the chemical composition and nutritional value of quinoa has been made, including its main nutritionally disadvantageous factors.

Finally, several traditional and new forms of using quinoa have been described. Some future perspectives with regard to the germplasm collection, agronomic and agricultural practices, postharvest and industrial uses of this promising grain, which has been called the "mother grain," have been included.

Origin and Distribution

Quinoa (*Chenopodium quinoa*, Willd) is an indigenous crop of the Andean region of South America. It is one of the oldest crops of the American continent. Archeological findings in northern Chile showed that quinoa was used prior to 3000 BC. In Ayacucho, Peru, evidence has been shown that quinoa was cultivated before 5000 BC.

The quinoa plant was widely cultivated in the entire Andean region, in Colombia, Ecuador, Peru, Bolivia, and Chile, before the Spanish conquest. However, habits and traditional foods of natives were substituted by foreign crops such as wheat and barley. Therefore, quinoa was cultivated either in small plantations in rural areas for domestic consumption or as borders for other crops such as potatoes or maize. For that reason, it was classified as food for poor people.

Quinoa is grown in the highlands from 5°N in southern Colombia to 30°S in northeastern Argentina. At sea level, it is cultivated between 36°S and 40°S, in central Chile.

In the late 1970s, the main production areas of quinoa were widely described in Colombia, Chile, the Andean valleys in Peru, Altiplano in Bolivia and Peru, and the highlands of Ecuador. In Peru and Bolivia, this crop has been of great importance. It is cultivated not only for domestic consumption but also for export. Common efforts made by governments and research institutes have contributed to increase the production of quinoa in Andean countries. The cultivation of quinoa has now spread from the Andean region to several countries in the world. In the 1980s, in the USA, quinoa was cultivated in the Colorado Rockies. Nowadays, it has became a commercial crop. In the UK, in 1989, quinoa was grown commercially. In Manitoba, Canada, quinoa was grown for domestic consumption; farmers expected to have a viable crop for Canada. Quinoa was introduced to Denmark in 1984. Further improvements in the crop could make quinoa a promising new crop for European agriculture.

In order to promote the regional interchange of the excellent genetic material of quinoa among research

institutes and universities, an American and European trial of quinoa was undertaken in the late 1990s. In the project, sponsored by the Food and Agriculture Organization (FAO: regional office for Latin America and the Caribbean), 25 cultivars selected from ten different countries were tested: eight from Peru, four from Bolivia, two each from Ecuador, the UK, Denmark, and Chile, and one each from Argentina, Brazil, Colombia, and The Netherlands. The best cultivar from each country taking part in the experiment was used as a local control. Therefore, it is expected to be able to identify, evaluate, and select promising genotypes of quinoa with high yield, and to provide the technological knowledge of cultivation practices and production of quinoa suitable for the agroecological and food requirements of the producer and national consumer.

Classification

Quinoa belongs to the Chenopodiceae family, genus *Chenopodium*. Its botanical name is *Chenopodium quinoa*, Willd. Common names used in the Andean region are: "quinua," "kiuna," "parca" (Ecuador, Peru, Bolivia); "supha," "jopa," "jupha," "jiura," "aara," "ccallapi," "vocali" (Bolivia); "quinhua" (Chile); and "suba," "pasca" (Colombia).

The classification of quinoa was first made from the color of the plant and fruits. Subsequently, it was based on the morphological types of the plant. Despite the wide variation observed, quinoa is considered to be one single species. For practical reasons, quinoa, like maize, was classified as a race.

The most extensive collection of different races of quinoa belongs to Peru and Bolivia; each has over 2000 ecotype samples. However, other collections do exist in Argentina, Colombia, Chile, Ecuador, England, the USA, and the Former Soviet Union.

Quinoa collected in Ecuador, Peru, and Bolivia has been classified into 17 races; however, more races may exist. Two types of inflorescence are described:

1. glomerulates – small groups of flowers (glomeruli) originate from tertiary axes;
2. amaranthiformes have glomeruli originating mainly from secondary axes.

According to this, the races of quinoa are classified as follows: first, glomerulate inflorescence: Cajamarca, Copacabana, Cuzco, Challapata, Cochabamba, Sicuani, Junin, Ancash, Glorieta, and Dulce; second, amaranthiforme inflorescence: Achacachi, Puno, Real, Potosi, Puca, Sucre, and Pichincha.

Quinoa grows from sea level to the Andean highlands. Thus, one of the most useful classifications is that describing five ecotypes: sea level, valley, subtropical, salar, and altiplanic (Table 1).

Cultivation Practices

The cultivation of quinoa is related to the crop rotation seen in potatoes. This is the usual practice that improves quinoa yield and preserves soil fertility. Moreover, the biological cycle of several pathogenic microorganisms is broken down. Together with residues of fertilizer previously applied to the crop, nitrogen is sometimes applied. Cultivation of the quinoa plant requires loose soil that can retain an adequate amount of moisture.

Quinoa tolerates a wide range of pH conditions of the soil, from pH 6.0 to 8.5. The plant is not affected by temperature from around −1°C. However, it tolerates high temperatures not above 35°C. Quinoa

Table 1 General categories of quinoa

Ecotypes	*Location*	*Growth altitude (m)*	*Varieties*	*Characteristics*
Sea level	South of Chile	<500	Chilean varieties	Unbranched, long day plants, yellow, bitter seeds
Valley	Andean valley	2000–4000	Blanca de Junín, Rosada de Juní, Amarilla de Matangani, Dulce de Quitopamba, Dulce de Lazo	Big plants, branched, short growth period
Subtropical	Subtropical area of Bolivia (Yungas)	2500–3000		Plants with intense green color that turn orange as they mature; small seeds, white or orange
Salar	Bolivian Salares	3700–3800	Real	Plants adapted to salty and alkalinic soils; bitter seeds; high saponin content
Altiplanic	Area around Lake Titicaca	3500–4000	Cheweca, Kancolla, Blanca de Julí	Short plants with straight stems; short growth period; resistant to frost

Reproduced from Encyclopedia of Food Sciences and Nutrition, 2nd Edition (2003), p. 4896, Elsevier Ltd.

is frost-resistant when the frost occurs before flowering; after that significant damage may occur. Quinoa flowers are sensitive to frost. Quinoa is drought-resistant. It is able to develop even in regions where annual rainfall is in the range 200–400 mm.

The planting season varies from August, in the Andean highlands, extending through December, and in some areas from January to March. Seeds may be spread, but weed control and mechanized practices become difficult. Quinoa is planted in rows (row spacing range 40–80 cm) when mechanized agricultural practices are used. In dry areas, seeds can be deposited at the bottom of the furrows; once planted, the seeds are covered with soil. When rain is more abundant, seeds are deposited on the top of the ridge.

Sowing density may vary according to the region. It has been reported from 0.4 to 0.6 $g\,m^{-2}$ in Bolivian Altiplano, from 0.5 to 2.3 $g\,m^{-2}$ in Puno, and from 0.8 to 1.4 $g\,m^{-2}$ in Ecuador. A density of 1.2 $g\,m^{-2}$ has been recommended in Puno for mechanical drilling. However, sowing density could be related to the climatic conditions of the region where it is cultivated.

At physiological maturity, quinoa is harvested. The grains become dry and hard, making it difficult to break them with a finger nail. Physiological maturity may be reached within 70–90 days after flowering. Depending on the variety, it takes between 5 and 8 months for a plant to mature.

Traditional harvesting is done manually. The plants are either pulled or cut with a sickle, then placed in windrows to dry completely. Threshing is performed by rubbing the panicles by hand against a stone or using threshing on the floor with sticks, animals, or vehicles followed by winnowing. Mechanical threshers have been applied using stationary threshers, some of which are adapted from those used for cereals. The yield of quinoa can be in the range of 45–500 $g\,m^{-2}$ depending on the variety and growing conditions.

The most important fungus disease is downy mildew (*Peronospora farinosa*), which requires high humidity and temperature as ideal conditions to grow. However, it succeeds in low humidity and low temperature (6–10°C) found in the north Altiplano. The main symptom is chlorotic lesions on the upper surfaces of the leaves, with a white or purple mycelium on the lower surfaces.

The disease brown stalk rot is produced by *Phoma exigua* var. *fovaeta*. Low temperature, high humidity, and wounds in the plant, such as those produced by hail, favor the growth of pathogen. Dark brown lesions with a vitreous edge (5–15 cm) on the stem and inflorescence are the main symptoms. The stem is often shrunken, the plant may become chlorotic, and progressive defoliation towards the apex may occur.

Kcona kcona (*Scrobipalpula* sp.) is probably the most serious pest of quinoa. When drought periods and high temperatures are present, insects attack intensely. Larvae first destroy leaves and inflorescence. Later on, when the plant is mature, larvae destroy the panicle and grains. Sometimes, a white powder around the base of the plant is seen as a result of grain destruction. Treatment is performed just before harvest to prevent contamination of seeds and consequently postharvest losses.

Morphology of the Plant

Quinoa is not a true cereal grain: it is a pseudocereal, which is dicotyledonous. In contrast, cereals are monocotyledonous. In spite of that, the composition of cereals and quinoa is similar as regards the main components.

Quinoa, as a plant, grows 1–3 m high (Figure 1). The seeds can germinate very fast, in a few hours after being exposed to moisture. Roots can reach depths of up to 30 cm. The stem is cylindrical (3–5 cm diameter); it can be either straight or with branches, and its color is variable. Depending on the variety, it changes from white, yellow, or light brown to red. Leaves are shaped like a goose's foot. They are formed by petioles and lamina; petioles are long-channeled on their upper side. Lamina is polymorphous in the same plant; rhomboidal or triangular in the lower lamina of leaves, triangular or lanceolate in upper leaves.

Figure 1 Quinoa plant. (Courtesy of Ing. Carlos Nieto C. Pronaleg-Iniap.)

The flowers are incomplete; they do not have petals. Quinoa has both hermaphrodite flowers, located at the distal end of a group, and female flowers located at the proximal end. Quinoa inflorescence is full of bunches (racemose), which emerge on the upper part and do not have branches. The arrangement of flowers in raceme is considered to be the panicle; the length of the panicle varies from 15 to 70 cm. Flowers can be clustered in different forms – either amaranthiforme or glomerulate.

Quinoa is a fruit of the Chenopodium family. The fruit of quinoa is an achene. It produces small, circular-shaped seeds, about 2 mm diameter (250–500 seeds per gram: Figure 2). It is covered by perigonium, which is the same color as the plant: white, yellow, gray, light brown, pink, black, or red. It is easily removed when it is dried. Another two layers enclose the seed. Pericarp adheres to the seed; it contains saponins which confer the bitter taste characteristic of quinoa. Episperm encloses the cylindrical seed as a thin layer. The embryo can be up to 60% of the seed weight. It forms a ring around the perisperm. The high protein content in quinoa, unlike cereals, is explained by the high proportion of embryo.

Chemical Composition and Nutritional Value

The diet of ancient inhabitants of the Inca empire has generated interest due to its extremely nutritious quality. Quinoa seeds contain carbohydrates, protein, fat, minerals, and vitamins. The chemical composition of quinoa depends on the variety and the environment of its cultivation.

Quinoa Seeds

Protein The protein content of quinoa seeds varies from 8% to 22%, which on an average is higher than common cereals such as rice, wheat, and barley (Table 2). However, it presents less than 50% of the protein found in most legumes. In quinoa, most of the protein is located in the embryo.

In pseudocereals, such as quinoa, albumins and globulins are the major protein fraction (44–77% of total protein), which is greater than prolamins (0.5–7.0%). Using a modified Osborne's method, protein fractions of quinoa were reported to be 75.1% of albumins + globulins and 19.4% of glutelins (insoluble); no prolamins were found. Thus, quinoa is

kcal 100 g^{-1}[a]	399	383	408	372	392	372	390	367	361	451

[a] kcal 100 g^{-1}: 4 × (%protein + carbohydrates) + 9 × (%fat).
[b] Source: Kent N (1983) Chemical composition of cereals. In: *Technology of Cereals*, 3rd edn., pp. 27–48. Oxford: Pergamon Press; Koziol MJ (1992) Chemical composition and nutritional evaluation of quinoa (*Chenopodium quinoa* Willd). *Journal of Food Composition Analysis* 5: 35–68.

considered to be a gluten-free grain because it contains very little or no prolamin. Quinoa provides a nutritional, economical, easy-to-prepare, flavorful food source which is of particular relevance for people with gluten intolerance, such as those with celiac disease.

Quinoa has a good balance of the amino acids that make up the protein. It is exceptionally high in lysine (Table 3), an amino acid which is not overly abundant in the vegetable kingdom. It is also a good complement for legumes, which are often low in methionine and cystine.

The nutritional evaluation of quinoa protein has been reported in several studies. The protein efficiency ratio (PER) in raw debittered quinoa was 78–93% that of casein. These figures increased when quinoa was cooked, and became 102–105% of those of casein. Similar results were found when quinoa from the San Luis Valley of Colorado was used. Thus, the quality of protein in quinoa matched that of the milk protein casein.

Carbohydrates The major component in quinoa is carbohydrates, which varies from 67% to 74% of the dry matter. Starch is about 52–60%. The starch compound is located in the perisperm of the seed; starch can be present as simple units or as spherical aggregates. The amylose content is about 11%, which is lower than in cereals, for example, rice (17%), wheat (22%), and barley (26%).

The diameter of quinoa starch granules is in the range of 0.4–2.0 μm. Starch granules in quinoa are smaller than those reported for maize (range 1–23 μm) and for wheat (2–40 μm). Small-granule starches often exhibit a higher gelatinization temperature; for quinoa the gelatinization temperature range is 57–64°C. Other carbohydrates are found in small amounts, such as monosaccharides (2%) and disaccharides (2.3%), crude fiber 2.5–3.9%, and pentosans 2.9–3.6%.

Fat, vitamins, and minerals Quinoa contains from 2% to 10% fat. Quinoa and soy oils exhibit similar fatty acid composition; thus, quinoa is a rich source of essential fatty acids such as linoleic (18:2*n*-6: 52%) and linolenic (18:3*n*-6: 4%). Quinoa is a good source of minerals. It contains more calcium, magnesium, iron, and zinc than common cereals, and the iron content is particularly high (Table 4). Polishing and washing quinoa seeds reduces the mineral content to some extent, 12–15% in the concentration of iron, zinc, and potassium, 27% loss of copper and 3% loss of magnesium. Quinoa contains more riboflavin (B_2) and α-tocopherol than rice, barley, or wheat (Table 4). Quinoa seeds can be a source of vitamin E.

Nutritional disadvantages Saponins and phytic acid are the main disadvantageous factors in quinoa. Other inhibitors, trypsin inhibitor, and tannins are present in low levels.

Trypsin inhibitor in eight varieties of quinoa (range 1.36–5.04 TIU mg^{-1}) was lower than for soybean (24.5 TIU mg^{-1}). Trypsin inhibitor is a thermolabile compound which is inactivated by heat treatments.

Polyphenols (tannins) are present in small amounts (0.53 g per 100 g in whole quinoa seeds), which are reduced after scrubbing and washing with water (0.23 g per 100 g).

Saponins A bitter taste compound called saponin is located in the outer layers of quinoa seeds. This protects them from birds and insects.

Saponins are glycoside compounds which occur in two groups. According to the nature of the sapogenin moiety, they are conjugated with hexoses, pentoses, or uronic acids. The sapogenins are steroids (C27) or triterpenoids (C30). Using a gas chromatography method, the sapogenins oleanolic acid, hederagenin, 30-*o*-methylspergulagenate, and phytolaccagenic acid are identifiable in sweet and bitter genotypes of quinoa.

Quinoa saponins are soluble in methanol or water. They have strong detergent properties which form very stable foam in water solutions, and reduce the superficial tension of aqueous solutions. They also show hemolytic activity and are in general toxic to cold-blooded animals which obtain oxygen directly from water. Saponins are also present in common foodstuffs such as peanuts, asparagus, garlic, onion, and spinach.

The amount of saponins present depends on the variety of quinoa. It is higher in bitter-flavor varieties than in sweet, or low-saponin, varieties. Quinoa comprises saponins from 0.1% to 5%.

The saponins of quinoa seeds are reduced to low levels after dry polishing and washing with water. These levels are apparently nontoxic to humans.

The reduction of plasma cholesterol and bile salt concentration has been attributed to the presence of certain saponins in the diet. However, some saponins can form insoluble complexes with minerals, such as zinc and iron, which make the minerals unavailable for absorption in the gut.

Phytic acid Phytic acid (myoinositol 1,2,3,4,5,6-hexakis dihydrogen phosphate) is found in most cereals and legumes at concentrations of 1–3% dry matter. It is also found in some fruits and vegetables.

In cereals, phytic acid is located in the germ. In quinoa seeds, phytic acid is located in the external layers as well as in the endosperm. It has been reported that mean (value) phytic acid concentration, in five varieties of quinoa, was 1.18 g per 100 g.

Studies *in vivo* and *in vitro* have shown that phytic acid interferes with mineral absorption in the gut of humans, because of its ability to form insoluble complexes with divalent minerals such as iron, zinc, and calcium. Even small amounts ($0.5\,\mu mol\,g^{-1}$) of inositol hexaphosphate or pentaphosphate may reduce the solubility of iron.

Inositol hexaphosphate (IP_6) was mainly found in varieties from Ecuador: sweet INIAP-Tunkahuan ($11.3\,\mu mol\,g^{-1}$) and bitter INIAP-Ingapirca ($8.6\,\mu mol\,g^{-1}$). These figures were almost completely reduced to $0.3\,\mu mol\,g^{-1}$ after fermentation of the germinated quinoa flour. At the same time a five- to eightfold increase in the amount of soluble iron was found.

Quinoa Leaves

The leaves of quinoa are compared to spinach as regards flavor. Quinoa leaves are cooked as a green vegetable or used raw in salad. Leaves contain (on a dry basis) carbohydrates 4.8 g per 100 g; protein 3.3 g per 100 g; fat 1.8 g per 100 g; ash 3.3 g per 100 g; fiber 1.9 g per 100 g. The protein concentration of quinoa leaves is similar to spinach; however, it contains slightly more isoleucine (5.8 g per 100 g protein) and valine (7.5 g per 100 g protein). The amount of fatty acids such as palmitic (16:0; 16.7%) and stearic (18:0; 1.3%) is higher than in the grains. Quinoa leaves are a rich source of vitamin A: they contain 2085 μg RE (retinol equivalents) per 100 g (fresh wt), and vitamin E 2.9 mg α-TE (alpha-tocopherol) per 100 g. Fresh quinoa leaves contain more magnesium (83 mg per 100 g fresh wt) and sodium (289 mg per 100 g fresh wt) than spinach leaves. Using a gas chromatography method, sapogenins were detected in the leaves of four sweet and bitter genotypes of quinoa. Sapogenins increased as the plant matured. After 120 days of sowing, the sapogenin content on the leaves of sweet genotypes varied between 0.013 and 0.017 g per 100 g (dry matter) and in bitter varieties varied between 0.02 and 0.16 g per 100 g (dry matter). Hederagenin was the major sapogenin present in the leaves.

Uses

Quinoa has a natural seed coating containing saponins, which encases the seed and confers the bitter taste which is characteristic of quinoa. Saponins must be removed before consuming. External coatings are removed using either a wet or dry process. The traditional wet process used in rural areas is hand scrubbing in alkaline water. This process is used on a commercial scale; it involves abrasive de-hulling to remove the external coverings, followed by a thorough washing. However, this method has economical and ecological restrictions: the water demand is high and waste water is contaminated with saponins, which are toxic to cold-blooded animals. Moreover, wet seeds must be dried immediately, or they may germinate after a few hours in wet conditions.

A dry method is also used. The seeds are scrubbed and polished in order to remove, as fine powder, external coatings. The equipment used to polish other grains has been adapted for use with quinoa seeds, with excellent results. This method presents several advantages; no water is needed, no heat treatment

to dry the seeds is required, and no environmental contamination is produced. This method is best suited to sweet varieties (low saponin content) of quinoa.

A combination of dry and wet processes is applied to bitter varieties (high saponin content) of quinoa. Saponin is first removed by polishing, when most of the saponin is removed. Then, saponins that remain in the seeds are washed with water, followed by a dry process. Any of the processes described above makes the quinoa ready for use by the consumer or further processing such as grinding.

After removing the saponins, quinoa seeds can be boiled in water (15–20 min) and served as a grain. Cooked seeds swell to about two or three times their original size. Seeds become transparent, with tiny white bands circling across the midsection.

In Chile, Ecuador, Peru, and Bolivia, the whole seeds are used in soups, salads, casseroles, chilli, and stew, as well as roasted and ground in several kinds of desserts.

Quinoa can be eaten as a rice replacement, as a hot breakfast cereal, or boiled in water to make an infant cereal. The seeds can even be popped like popcorn. Seeds can be ground and used as a flour, or sprouted. The sprouts need to turn green before they can be added to salads.

Quinoa flour can be mixed with maize or wheat flour. Several levels of substitution of quinoa flour have been reported, for instance, in bread (10–13% quinoa flour), noodles, and pasta (30–40% quinoa flour) and sweet biscuits (60% quinoa flour). All yield products of excellent quality. Quinoa flour can also be drum-dried and extruded, providing products with good physical, sensorial, and nutritional qualities. Solid-state fermentation of quinoa with *Rhizopus oligosporus* Saito was performed, giving a good-quality tempeh.

In Bolivia, in 1975, the government adopted a resolution mandating that 5% of quinoa flour must be added to all pastas, crackers, and breads.

Leaves, like the seed, can also be cooked, made into a spinach-like dish, or may be served raw in a salad. Tonics, puddings, and syrups can also be prepared from the leaves. The foaming qualities of saponin are sometimes used to produce a frothier "chicha."

In industry, saponins from quinoa have multiple purposes. They are used as soap for washing hair or clothes, in a compound for a fire extinguisher, or in photo processing. Dried stalks of the plant are used as fuel, or may be used in preparing bleach or dyes.

Future Perspectives

The nutritional excellence of quinoa has been known since ancient times in the Inca empire. Nowadays, quinoa has been recognized for its nutritional benefits all over the world, and for its protein, mineral, and vitamin content.

The importance that quinoa could play in nutritional behavior is being emphasized, not only in developing countries but also in the developed world. In the Andean countries, quinoa crops could play an important role in the future of their economies, giving a new export market, as well as in national subsistence. Moreover, quinoa could be a strategic crop used to complement the diet in rural/marginal regions where energy-protein malnutrition affects most of the population of the developing countries. Quinoa, as the "mother grain," represents an exotic and healthy rediscovery in the developed world.

Germplasm collection should continue in countries of the Andean region. Agronomic research, including plant density, potential cultivation, phenology, morphology, physiological maturity, yield, and weed control, should be performed. Further research is needed in order to study the adaptability of different cultivars to "new homes of quinoa" in the USA and Europe. Using mechanized agriculture may facilitate mechanical harvesting of the grain, reducing postharvest losses.

Improving methods for removing saponins without significant modification of nutritive value are encouraged. The selection of sweet genotypes with a very low saponin content in the seeds, large grain, and high yield are the main breeding goal. Sweet genotypes could be selected early in plant development in order to speed up the selection process. Further research is needed to find markers for indirect selection for sweet genotypes.

The need for intensive cultivation of quinoa should be emphasized; this could meet quality and quantity needs by the food industry. Besides, aggressive promotion campaigns should be carried out to encourage greater consumption of the grain. Finally, quinoa is being promoted as an extremely healthy food – a supergrain – of the future (gluten free). It is a food of the twentyfirst century.

RESEARCH ORGANIZATIONS OF THE WORLD

Contents

Europe and North America

J H Skerritt, Australian Centre for International Agricultural Research, Canberra, ACT, Australia

Introduction

This article describes the activities of some of the major research institutes in Europe and North America in the area of grain science. There is a deliberate bias towards provision of more detailed information on institutions in English-speaking countries, reflecting the main readership of this article. Compared with the long history of cultivation of grains (many thousands of years), use of research principles to address constraints is a comparatively recent approach. Agricultural societies were established in the UK, France, and Germany in the mid-1800s (e.g., The Royal Agricultural Society of England (1839); La Société des Agriculteurs de France (1850); Deutsche Landwirtschafts-Gesellschaft (1885)) and by the mid-late nineteenth century agriculture experiment stations were appearing in Europe and North America. The tradition of government-funded grains research is longest established in Europe and North America, although similar initiatives were started in the late nineteenth century in a number of European colonies.

A number of trends are identified, including the move towards formation of networks between research institutes as well as the shift in focus of several grain R&D institutions from a largely production focus to an emphasis on environmental issues such as water-use efficiency and sustainability of farming systems. Other consistent trends include the greater importance of levies from grain-growers in supporting research in a number of countries (e.g., since 1959 in France), and the increase in commercial involvement in grain breeding and biotechnology. Government-funding bodies have also shown a greater interest in assessing the impacts of research that they fund, including carrying out more economic analysis of projects – research is increasingly viewed as an investment rather than as "grants." The most significant trend in terms of research intensity is the very significant growth over the last couple of decades in the level of grains R&D carried out by the private sector. Most publicly-funded agricultural research in North America and Europe is concentrated in the US, France, and Germany, with the UK and Canada having smaller roles. There is also a much greater proportion of agricultural (including grains) research

carried out in universities in Europe and North America compared with developing countries, where it is overwhelmingly within government-funded research institutes. Grains R&D carried out by commercial and industry organizations is reviewed in a separate article (*see* **Research Organizations of the World**: Global Trends and the Commercial Sector).

Taxonomy of Research Institutions

Major Public Sector (Government and University) Grain Science Organizations

USA The USA has very large private sector (seed companies, milling, baking, brewing, and oilseed processing companies, and biotechnology companies) and government investments in grains R&D. A wide range of temperate grain crops are targeted – especially wheat, barley, maize, oilseeds, and pulses (also subtropical rice), with most resources dedicated to maize and wheat research. Both state and federal governments invest in agricultural research, with the federal investment being slightly higher.

The Agricultural Research Service (ARS) is the principal in-house research agency of the (National) US Department of Agriculture (USDA), and together with the "land grant" universities form the main research centers for grains research. In the past, there has been comparatively limited interaction and coordination between different USDA centers carrying out grains research, although the development of a "national program" structure by USDA-ARS in recent years has increased the amount of coordination. Most of the grains research activities are within the "crop production, product value, and safety" cluster of programs. Some of the major objectives of USDA grains research include:

- crop improvement, integrated crop production systems;
- crop protection and quarantine;
- crop genetic resources, genomics, and genetic improvement;
- fundamental research on plant productivity and quality and plant-pathogen interactions; and
- postharvest quality-maintenance, environmentally friendly efficient-processing, and value-added products including the use of grain crops as biofuels.

Some USDA centers are free-standing multidisciplinary USDA research centers while others are colocated on university campuses. Many centers have the mandate to carry out research directed at the particular agro-ecological zone in which the institute is based. For example, wheat is grown in many parts of the US, but there are different quality types suited for different locations – Soft Red Winter Wheat in the Midwest, Virginia, and North Carolina; Hard White and some Hard Red Winter Wheat in Pacific Northwest, Hard Red Winter varieties in the Great Plains, from Texas to Montana on the Canadian border, and Spring varieties in northern central states such as Minnesota, North, and South Dakota and Montana – and appropriately located USDA centers develop germplasm and agronomy packages for the different types of varieties. Some of the major USDA centers carrying out grains research, shown in alphabetical order of location, are based in:

- Aberdeen, ID: small grains and potato germplasm research;
- Albany, CA (Western Regional Research Center): genomics and gene discovery; crop improvement/utilization; plant mycotoxins;
- Ames, IA: corn insects and crop genetics;
- Beltsville, MD: (Beltsville Agricultural Research Center) Sustainable Agricultural Systems Laboratory; Instrumentation and Sensing Laboratory; National Germplasm Resources Laboratory; Soybean Genomics and Improvement Laboratory;
- College Station, TX (Southern Plains Agricultural Research Center): crop germplasm and insect pest research;
- Colombia, MO: plant genetics research;
- Corvalis, OR: forage seed and genetics research;
- Fargo, ND (Red River Valley Agricultural Research Center): cereal crops research, wheat quality;
- Fort Collins, CO: National Center for Genetic Resources Preservation;
- Ithaca, NY: plant genetic resources, plant protection research;
- Lane, OK (Southern Central Agricultural Research Laboratory): genetics and production research;
- Lincoln, NE: wheat, sorghum, and forage research;
- Lubbock, TX: Cropping Systems Research Laboratory;
- Madison, WI: cereal crops research;
- Manhattan, KS (Grain Marketing and Production Research Center): biochemical and structural aspects of grain quality, stored grains entomology, fungal diseases, plant physiology of cereals;
- Peoria, IL (National Center for Agricultural Utilization Research): cereal products and food science research, plant polymer research, mycotoxin research, new crops processing research;
- Raleigh, NC: soybean and nitrogen fixation research, basic plant science;

- Shafter, CA: western integrated cropping systems research;
- Stillwater, OK: plant science and water conservation research;
- Stoneville, MS: crop genetics and production research;
- Stuttgart, AR: Dale Bumpers National Rice Research Center;
- Tifton, GA: crop genetics and breeding research, crop protection and management research;
- Urbana, IL: soybean/maize germplasm, pathology, and genetics research;
- Wooster, OH: soft wheat quality research, corn, and soybean research; and
- Wyndmoor, PA: crop conversion science and engineering.

USDA also has a (smaller) Economic Research Service, which carries out research and communication activities in many areas relevant to grains, including farm-level risk management, commodity outlook research, and research on marketing and production sustainability. The USDA Federal Grain Inspection Service has a technical center in Kansas City, MO, which validates equipment and methods for grains analysis.

The "land grant" college system was established in 1862 under the Morrill Act, in the same year that USDA was established – the name is derived from the fact that the colleges were originally endowed by grants of public lands in the expanding western United States. The 1887 Hatch Act established the agricultural experiment station system to enable these colleges to undertake research, and the 1914 Smith–Lever Act established the cooperative extension system. This unique system has the advantage of linking state government R&D and extension activities to university research. At the federal level, land grant university programs are supported through the USDA Cooperative Research, Education, and Extension Service. Universities have anywhere from a few to over a dozen discrete experiment stations at different locations in their state, again often corresponding to different agro-ecological zones, but also allowing researchers to carry out a local outreach function. Usually a significant proportion of the researchers – maybe half – are located on the main university campus and the rest throughout the state. There is usually a balance of applied grains research on constraints to productivity in the particular state and a proportion directed towards more fundamental research. Cooperative extension systems from land grant universities have a state development mandate and often involve location of farm advisors in counties throughout the state. Virtually all US states have one (and in some cases, two) land grant universities, and about half of them have strong grains research activities, usually across several departments rather than in a single program. A summary of some of the main US universities that carry out grains research is provided in Table 1. Land grant universities are usually predominantly state-funded, but with significant federal funding as well.

Canada The Canadian Grains Commission in Winnipeg, Manitoba regulates grain handling and establishes and maintains grain quality standards for Canada. Its Grain Research Laboratory has emphasis on understanding the genetic, environmental, structural, and biochemical basis on end-use quality of major Canadian grains, including bread and durum wheat, barley, oilseeds, and pulses (peas, lentils, chickpeas, and beans). There is a special focus on analytical methods and processing technologies. The Canadian International Grains Institute, also in Winnipeg has a technical training and information dissemination role.

Agriculture and Agri-Food Canada carries out grains research at several of its 19 research centers across the country. Cereal research is carried out mainly at the Winnipeg (Manitoba) Cereal Research Centre emphasizes the development of bread and durum wheat and oat varieties for the prairies, with research strengths in genetics, biotechnology, plant pathology, cereal chemistry, and quality evaluation. There are also active research groups on grain and oilseed storage and insect pests of stored commodities. The Eastern Cereal and Oilseed Research Centre (Ottawa, Ontario) develops new varieties of wheat, barley, corn, oats, and soybeans along with crop protection and management systems. Wheat breeding is also carried out at the Semi-arid Prairie Agricultural Research Centre (Swift Current, Saskatchewan) and the Lethbridge Research Centre (Kamloops, Alberta). There is an emphasis on disease and disease resistance as well as agronomy. The Brandon Research Centre (Brandon, Manitoba) is the main site of barley breeding, while the Lacombe Research Centre (Lacombe, Alberta) undertakes oat-varietal improvement research.

The Saskatoon Research Centre (Saskatoon, Saskatchewan) is the main center of breeding programs for canola and mustard and conserves many of the grains genetic resources of Canada. Some canola breeding also takes place at the Lacombe Research Centre, while the Greenhouse and Processing Crops Research Center also carries out soybean breeding. Agronomy research for grains production is undertaken at Soils and Crops Research and

Table 1 Some United States universities undertaking significant grains research

University (website)	*Grains research emphasis*
Colorado State University, Fort Collins, CO; College of Agr. Sci. (www.agsci.colostate.edu)	Genomics, biotechnology, dryland farming systems, wheat breeding, precision agriculture
Cornell University, Ithaca, NY; College of Agr. and Life Sci. (www.cals.cornell.edu)	Genetics, biotechnology, basic plant science, maize breeding, seed science, cereal pathology, cereal product rheology
Iowa State University, Ames, IA (www.ag.iastate.edu)	Corn and soybean breeding, nonfood crop products, corn quality, basic plant sciences, crop genomics, seed technology
Kansas State University, Manhattan, KS (www.oznet.ksu.edu)	Wheat, soybean, and sorghum breeding; cereal (wheat, corn, sorghum, millet) agronomy and physiology, entomology, cereal chemistry, milling and baking, livestock feeds
Michigan State University, East Lansing, MI (www.maes.msu.edu)	Grain crop breeding, cereal chemistry, genomics
Montana State University, Bozeman, MT; College of Agr. (www.montana.edu/agriculture)	Winter wheat, barley, durum, pulses, canola, and soybean breeding, precision agriculture, integrated pest management
North Carolina State University, Raleigh, NC; College of Agr. and Life Sci. (www.cals.ncsu.edu)	Bioinformatics, integrated pest management
North Dakota State University, Fargo, ND; College of Agr., Food Systems and Nat. Res. (www.ag.ndsu.nodak.edu)	Basic research on wheat quality and processing; milling; pasta production; brewing; farming systems, pathology, and entomology
Oklahoma State University, Stillwater; Div. of Agr. Sci. and Nat. Res. (www1.dasnr.okstate.edu)	Baking, grain protein chemistry, oilseed chemistry, plant diseases
Ohio State University, Columbus, OH; Ohio Agr. R&D Center (www.oardc.ohio-state.edu)	Maize production systems, cereal and oilseed quality, Soft Red Winter Wheat and soybean agronomy and breeding, soy protein functionality
Pennsylvania State University, Univ. Park, PA; College of Agr. Sci. (www.research.cas.pse.edu)	Starch chemistry, entomology
Purdue University, West Lafayette, IN (www.agriculture.purdue.edu/arp)	Plant stress physiology, biotechnology, integrated pest management, precision agriculture, new grain products, carbohydrate research
Rutgers University, New Brunswick, NJ; Center for Adv. Food Tech. (www.foodsci.rutgers.edu/caft) NJ Agr. Experiment Station (www.cook.rutgers.edu)	Cereal processing, plant biotechnology
Texas A&M University, College Station, TX (www.agresearch.tamu.edu; www.agrprogram.tamu.edu)	Precision agriculture, farming systems, plant genomics, grain food processing
University of Arkansas, Fayetteville, AR; Dale Bumpers College of Agr. Food and Life Sci. (www.uark.edu/admin/aes)	Rice, wheat, oat, and soybean breeding; agronomy and physiology, rice processing
University of California, Davis College of Agr. and Environ. Sci. (www.ucanr.org; www.caes.ucdavis.edu)	Genetic resources conservation, genetics of cereals and legumes, agronomy, wheat breeding, entomology, plant pathology, rice breeding (with California Rice Exp. Station and USDA)
University of Illinois, Urbana-Champaign, IL (www.web.aces.uiuc.edu)	Maize and soybean breeding and agronomy, cereal diseases, starch chemistry
University of Idaho, Aberdeen, Moscow College of Agr. and Life Sci. (www.ag.uidaho.edu)	Grains breeding and agronomy (wheat, oilseeds)
University of Minnesota, St. Paul, MN; Colleges of Agr., Food and Environ. Sci. (www.maes.umn.edu)	Cereal structure, wheat and barley breeding and pathology, soybean diseases, precision agriculture, cereal food processing
University of Missouri, Colombia, MO; College of Agr., Food and Nat. Res. (www.cafnr.missouri.edu)	Tillage, soybean, sorghum, and corn cropping systems and soybean breeding, basic grain science, maize genome mapping (Donald Danforth Center, St. Louis, MO)
University of Nebraska, Lincoln, NE Institute of Agr. Natural Res. (www.ard.unl.edu)	Processing of grain starches, cereal breeding, genomics
Washington State University, Pullman, WA; College of Agr. and Home Econ. (www.cahe.wsu.edu)	Grain crops breeding and genetics, pathology/entomology, soil science, processing

Development center (Sainte-Foy, Quebec), Crops and Livestock Research Center (Charlottetown, Prince Edward Island), the Brandon Research centre, and the Semi-arid Prairie Agricultural Research Centre.

Several universities carry out grains research in Canada, and in some cases individual departments and staff interact closely with Agriculture Canada scientists. These include:

- University of Manitoba, Winnipeg, through its Faculty of Agricultural and Food Sciences carries out research on canola and wheat breeding and postharvest technology, grain storage technology, cereal chemistry, baking technology, pulse food science, functional foods, and cereal agronomy including precision agriculture.
- University of Saskatchewan, Saskatoon, through its College of Agriculture has a research emphasis on wheat, barley, oat, canola, and legume (lentil, pea, dry bean, and chickpea) breeding and agronomy, plant genetic engineering, molecular marker development, and malting and brewing science.
- University of Alberta, Edmonton, through its Department of Agricultural, Food and Nutritional Science conducts studies on grain and oilseed crops for Western Canada – breeding, disease resistance, agronomy, and livestock feed utilization.
- University of Guelph, Ontario, through its Department of Plant Agriculture emphasizes grain crops breeding (soybean, barley, wheat, and canola), agronomy, pathology, and genome mapping.
- McGill University, Quebec, Ontario, through its Faculty of Agricultural and Environmental Sciences, is involved with basic plant science, biotechnology, and some grains food processing research.

The National Research Council (NRC) Plant Biotechnology Institute in Saskatoon carries out basic research in genomics and proteomics, and has a special interest in the modification of oil composition and of agronomic traits of oilseeds, as well as in cereal and legume molecular marker and transformation technology. Some individual provinces also have agencies that carry out applied agriculture and food research.

Mexico In Mexico, maize is the main grain crop but the national program played an important role in semi-dwarf wheat breeding ahead of the establishment of CIMMYT. Most federal government agricultural research is carried out by the Instituto Nacional de Investigaciones Forestales Agricolas y Pecuarias (INIFAP); some of the state governments have small grains research activities. There is also significant activity within the higher education and science and technology ministries Consejo Nacional de Cienia y Tecnologia (CONACYT), with grains research being carried out in several of their regional centers (Centro de Investigacion en A, limentacion Y Desarrollo AC (CIAD), Centro de Investigacion Y Assistencia en Tecnologiia Y Diuseno del Estado de Jalisco (CIATEJ), Centro de Investigaciones Biologicas del Noreeste (CIBNOR), and El Colegio de la Frontera Sur (ECO SUR)). Postgraduate colleges, within the universities managed under the agriculture secretariat (SAGAR), along with the agronomy faculties in autonomous universities in different Mexican states are also active. Mexico is home to a number of national seed companies (maize, sorghum, wheat), along with subsidiaries of foreign (especially US) seed companies and these carry out variety trials and agronomy work.

Western Europe In Western Europe, yields of most major cereals are high, and it is clear that there has been a shift away from research on increasing production to an emphasis on environmentally friendly production. Other research areas include:

- quality and processing technologies, including value-addition and nonfood uses of grains;
- food safety, nutrition, and health – with grains the main emphasis is on mycotoxins, nutraceuticals, dietary fiber, and allergies and intolerances;
- traceability – e.g., of GM cereals; and
- breeding, genomics, and diagnostic technologies.

Among the United Kingdom government institutes, the Biotechnology and Biological Sciences Research Council (BBSRC) places some emphasis on research on grains, with several of its eight institutes involved in the research program. These institutes and their research areas include:

- John Innes Centre, Norwich – starches, plant biotechnology, fundamental biology of cereals and brassica crops;
- Institute of Food Technology, Norwich – basic food science, including research on grain foods ingredients stricture, protein functionality in breadmaking quality, and allergenicity;
- Silsoe Research Institute; and
- Institute for Arable Crops Research (recently renamed Rothamsted Research after consolidation of the Rothamsted and Long Ashton sites) – grain crop performance and improvement, disease management, invertebrate pests, and weeds of grain crops and crop-environment interactions.

The former Ministry of Agriculture, Fisheries and Food (now known as the Department for Environment, Food and Rural Affairs) is directly responsible for the Central Science Laboratory in York. The Laboratory has an emphasis on food safety and quality, pest and disease management in crops and chemical residues. The Department also carries out some research on sustainability of grain-based farming systems in the UK. There is a separate Department of Agriculture for Scotland, with two relevant institutes, the Rowett Research institute (food processing, nutrition, biotechnology) and the Scottish Crop Research Institute (cereal quality and nutrition, cereal and brassica breeding, plant pathology).

Major British universities carrying out research in grain science include:

- University of Reading has research programs on agriculture-environment interactions, crop protection, crop breeding and agronomy, seed science, farming systems, and cereal chemistry;
- University of Nottingham, Sutton Bonington has programs in basic plant sciences, agriculture and food sciences, including agronomy of temperate and tropical cereals, and research on grain crop abiotic field stress;
- University of Bristol, Long Ashton;
- University of East Anglia, Norwich carries out research on cereal molecular biology;
- Heriott-Watt University, Edinburgh, Scotland;
- University of Plymouth, Devon;
- University of Leeds, Procter Department of Food Science;
- University of Manchester Institute of Science and Technology, Satake Centre for Grain Process Engineering;
- University of Wales, Centre for Arid Zone studies; and
- Queen's University Belfast, The School of Agriculture and Food Science – plant pathology, grain crop physiology, aflatoxins, oat quality.

The Home-Grown Cereals Authority is an organization funded on grower levies to support research, provide market information and extension information for British grain farmers.

In France, the Institut National de la Recherche Agronomique (INRA) is the main government research organization in agriculture and grains research. INRA has a large center in Nantes with a research emphasis on agriculture and food processing. There is an additional emphasis on cereal food and nutritional quality and nonfood uses, with a strong emphasis on processing technologies and basic protein and starch molecular sciences related to cereals. At INRA Montpelier, there is also on-going research on processing technology, grain crop production systems, plant protection, and genetic resource conservation as well as more basic studies on grain crop development. Centre de Cooperation Internationale en Recherche Agronomique pour le Developpement (CIRAD) is a foreign-aid organization that carries out research both within France and in developing countries. CIRAD has well-founded programs covering production and postharvest technology of rice, maize, and tropical grain legumes, research on soil and water management for crop production, and strong molecular marker/biotechnology programs. Auvergne is a partnership involving private companies such as Groupe Limagrain and public organizations such as INRA, and have established a cereal genotyping laboratory to form a link between breeding and genomic research. Several French universities have Ecole Nationale Superieure Agronomique – for example in Paris-Grignon, (the Institut National Agronomique (INA-PG)), in Montpellier, Rennes, Nancy, and Toulouse. ARVALIS Institut du végétal is responsible for Applied Research on cereals, maize, pulses, potato, and forage crops. The activities of this technical institute, which is run and financed by farmers, include sustainable cropping systems, precision farming, remote sensing, satellite images, biotechnology, farm economics, quality assurance, safety quality, traceability, human food, animal feed, and technology transfer. CETIOM is responsible for similar topics on oil crops.

In Germany, the Federal Ministry of Food, Agriculture and Forestry has several relevant institutes – the federal institute for Grain, Potato, and Lipid Research (BAGKF, Detmold), the Federal Research Centre for Plant Breeding (BAZ), the Federal Research Institute for Nutrition (BFE), and the Institute of Agricultural Engineering (ATB, Potsdam-Bornim). There is also an institute for Plant Genetics and Crop Plant Research (IPK, Gatersleben). At least two of the Max Planck institutes undertake grains research – the Institute of Plant Breeding in Cologne and the Institute of Molecular Plant Physiology in Golm. Many of the German states have research agencies or centers in agriculture and several of these carry out grains research, sometimes in conjunction with universities. Universities carrying out grains research include Humboldt University, Technical University of Berlin, Technical University of Munich, and the Universities of Bonn, Goettingen, Hohemheim, Kassel, Kiel, Rostock, and Paderborn.

In Ireland, the Irish Agriculture and Food Development Authority (TEAGASC) has nine research centers. The Oak Park Research Centre emphasizes research on grain crops, especially aiming for more efficient production systems for cereals, grain lupins,

and rape oilseed. There is a strong emphasis on the management of fungal and viral diseases of cereal crops. The main university for production research on grain crops is University College Dublin, while University College Cork emphasizes grains processing research.

In Switzerland, the major government grains research institutes are the Federal Office of Agriculture Research Station for Plant Production and Research Station for Agro-ecology and Agriculture, while in the university sector the Swiss Federal University for Technology in Zurich carries out most of the applied grains sciences research.

The Cereal Institute, National Agricultural Research Foundation (NAGREF), Thessaloniki, Greece is the Greek government research institute responsible for cereal breeding and cereal food product development. However, the Ministry of Agriculture has a separate research service with a network of institutes in different parts of the country. At least three universities carry out some grains research work – Agricultural University of Athens, Aristotle University of Thessaloniki, and the Mediterranean Agronomic Institute at Chania. In Hungary, the Ministry of Agriculture and Rural Development manages the Central Food Research Institute (KEKI) and the Agricultural Biotechnology Center (MBK), as well as the Cereal Research Institute in Szeged. The Hungarian Academy of Science has several institutes relevant to grain science – the Agricultural Research Institute, the Research Institute for Soil Science and Agricultural Chemistry, and the Plant Protection Institute. Universities with research areas most relevant to grain science are the Technical University of Budapest (grains processing), the Universities of Agricultural Science at Godollo, Debrecen, and Pannon. In Austria, the Federal Ministry of Agriculture and Forestry has research institutes for general agriculture as well as an Institute of Cereal Processing, Applied Soil Science and Agricultural Engineering.There is also a University of Agriculture, Forestry and Natural Resources in Vienna. In the Czech Republic, relevant Ministry of Agriculture research institutes include the Food Research Institute, Research Institute of Crop Production, Research Institute for Soil and Water Conservation, and Research Institute of Agricultural Engineering. There are semicommercial institutes responsible for cereals (Kromeriz Ltd.), Oilseed crops (Oseva Ltd.), and brewing and malting. Two universities – Mendel University of Agriculture and Forestry and Czech University of Agriculture – are relevant to grains research.

In the Netherlands, several institutes within the government Department of Agricultural research (DLO) carry out grains research – including the Agrotechnological Research Institute (ATO – cereal chemistry and processing), Plant Research International, and Applied Plant Research Institute (PPO). Wageningen Agricultural University is the main university research center for grains research. In Belgium, there are relevant government agricultural research centers in Gent and Gembloux, while at least four universities carry out some aspects of grains production and processing research – Ghent, Leuven Catholic University, Gembloux, and Louvain-la-Neuve.

The Italian government Ministry of Agriculture and Forestry has several research institutes covering grains research, including the Research Institutes for Cereals (ISC), Industrial Crops, Plant Nutrition, Plant Pathology and Food and Nutrition (IMRAN). The National Research Council (CNR) has a separate system of research institutes, and some of these also carry out grains research. Many major states in Italy host universities which have agriculture faculties, and most of these carry out at least some grains research – Turin, Milan, Padua, Udine, Bologna, Piacenza, Florence, Pisa, Ascoli, Peruge, Viterbo, Naples, Bari, Potenza, Reggio Calabria, Catania, Palermo, and Sassari.

In Sweden, the Government Swedish Institute for Food Research and the Swedish Institute for Food and Biotechnology (SIK, a joint industry/government body) carry out grains processing research. Production research and basic scientific investigations within universities include the Swedish University of Agricultural Sciences at Svalov and Lund University. Three main institutes in Norway carry out grains research. Within the government Ministry of Agriculture, there is the State Agricultural Research Station (SFL) and the Agricultural University of Norway at Aas, while MATFORSK, the Norwegian Food Research Institute is a nonprofit organization.

In Finland, the Ministry of Agriculture and Forestry has the Agricultural Research Centre of Finland and Plant Breeding Institute, while VTT Biotechnology in Espoo carries out cereal technology research in close collaboration with industry. The University of Helsinki is the main higher education center dealing with grains research. In Denmark, the Ministry of Food, Agriculture and Fisheries has Institutes in Agricultural Sciences and Agricultural Engineering. The Royal Veterinary and Agricultural University also carries out grains research. Activities related to the Carlsberg laboratory are described in **Research Organisations of the World**: Global Trends and the Commercial Sector.

In Spain, the Ministry of Agriculture, Fisheries and Food runs the National Institute of Agricultural and Food Technology (INIA), while the Madrid Polytechnic University has a large faculty involved with research in agriculture. There is also an INIA in

Portugal, while agricultural research is carried out at the Technical University of Lisbon, the Universidade de Tras-os-Montes e Alto Douro, and Universidade dos Ascores.

In Russia, the Russian Academy of Agricultural Sciences comprises about 200 institutes. These include All-Russia Research Institutes (e.g., Plant Quarantine (Bykovo), Plant Protection (St. Petersburg), Biological Plant protection (Ekaterinburg) which carryout entomology research related to grains) and Regional Research Institutes in former republics. The latter often cover a range of agricultural disciplines and some have an almost 100 year history; many have significant grain breeding and seed distribution programs. Three of the All-Russian Research Institutes most relevant to grains are the Institute of Legumes and Groat Crops (Streletskoye), Institute of Sorghum and Cereals (Zernograd), and The N.I. Vavilov Institute of Plant Industry. The latter institute, based in St. Petersburg, but with a number of experimental stations throughout Russia, is the main internationally renowned Russian institute emphasizing the conservation and study of plant genetic resources, including grain crops. Most states have State Agrarian Universities and there are a small number of specialist agrarian academies including Moscow Agricultural Academy.

After separation from Russia in 1991, National Agricultural Research Systems developed in most of the former Soviet Republics using the institutional assets left by the former USSR; several of these have a strong crops research emphasis although resources for research are very limited and it has been difficult (and often undesirable) to maintain the staff numbers and infrastructure left behind. They have had to develop their priority setting to match specific requirements of their agro-ecological zone and changed policy/economic environment including a greater emphasis on markets.

J H Skerritt, Australian Centre for International Agricultural Research, Canberra, ACT, Australia

Introduction

This article describes the activities of some of the major research institutes active in grain science in regions other than North America and Europe. These countries vary significantly in their state of development, and correspondingly in the development of their grains research capacity. Furthermore, grains research in some countries such as China has advanced so much since 1980s that in some areas, such as biotechnology and the development of hybrid rice, pioneering work in the area of R&D is carried out. The national agricultural research systems (NARS) of countries such as China, India, and Brazil are now among the largest institutions internationally and thus make an increasing input to international grain science efforts. On the other hand, capacity for grains research (and agricultural research in general) has fallen in many African countries. There is a special effort to review relevant international agricultural research centers. While attempts are made to review organizations that carry out grains research worldwide, there is a deliberate bias toward provision of more detailed information on institutions in English-speaking countries. This article focuses on government and public sector research institutes; private sector research is reviewed in the next article. **Research Organizations of the World**: Global Trends and the Commercial Sector.

Many of the trends in North America and Europe are reflected in both the developed and developing countries in these regions. In Australia especially, there has been a move towards formation of networks between research institutes. Other trends in Australia include the greater importance of levies from graingrowers in supporting research in a number of countries, and the increase in commercial involvement in grain breeding and biotechnology. More broadly, across each of the regions reviewed, is a shift in focus of many of the grain R&D institutions from a largely production focus to an emphasis on environmental issues such as water-use efficiency and sustainability of farming systems. For the developing countries that benefited from the higher-yielding varieties of the "Green Revolution," sustaining the gains through more efficient use of water and prevention of erosion, waterlogging, salinity, and acidification is now critical. Also critical is research on grain quality and addressing market requirements, as grain production in several of these countries struggles to compete with subsidized European and US agriculture.

The International Agricultural Research Centers

The CGIAR system (Consultative Group for International Agricultural Research) is a nonprofit network of 16 semiautonomous R&D centers, supported by the World Bank and a range of national Governments, usually through their overseas development assistance programs. Several of the centers have a grain science

focus, including the first two centers that were established in the early 1960s, International Rice Research Institute (IRRI) and Centro Internacional para Mejoramiento del Mais y Trigo (The International Maize and Wheat Centre – CIMMYT). CIMMYT is based in Mexico, but has programs in Latin America, Africa, Central Asia and West Asia, and North Africa. Other CGIAR centers with a strong grains focus include International Crops Research Institute for the Semi-Arid Tropics (ICRISAT) in Patancheru, India (focusing on sorghum, pearl millet, chickpea, pigeon pea, and peanut) and International Center for Agricultural Research in the Dry Areas (ICARDA) in Aleppo, Syria (focusing on barley, wheat, lentil, faba bean, chickpea, forage legumes).

Three centers carry out studies on rice improvement. IRRI, centered at Los Banos, Philippines is the main one, and its work aims to help poor farmers in developing countries grow increased yields of rice using less water, less labor, and fewer chemical inputs. The semidwarf rice varieties and management packages developed by IRRI were central to the successes of the Green Revolution in the 1960s and 1970s. IRRI has a focus on Asia while two other centers undertake rice breeding and management in Latin America and Carribean (International Center for Tropical Agriculture – CIAT, in Cali, Colombia) and West Africa (Western Africa Rice Development Association – WARDA, in Bouake, Cote de Ivore).

The CGIAR centers have traditional strengths in germ plasm development, providing much of the germ plasm for development of the modern varieties now utilized throughout the developing world (as well as in some developed countries such as Australia). To support germ plasm development, centers have strengths in agronomy, quality assessment, biotechnology, pathology, natural resource management, and economics. Conservation of genetic resources is an important part of the centers' mandates. At CIMMYT, wheat and maize breeding (agronomy and quality evaluation programs) are backed up by programs in economics, natural resource management, and biotechnology. ICRISAT has a geographical emphasis on south Asia and sub-Saharan Africa, and its research addresses water scarcity through natural resource management (rainwater conservation and utilization) and plant breeding to improve water-use efficiency and drought tolerance. ICARDA has a geographical emphasis on central west Asia and northern Africa, but its germ plasm is utilized worldwide. ICARDA focuses on agriculture in tropical dry areas, while ICRISAT emphasizes temperate and subtropical dry areas. It also has an emphasis on water-soil management in integrated farming systems for low-rainfall areas. The International Institute of Tropical Agriculture (IITA) with headquarters in Ibadan, Nigeria focuses on germ plasm (including several grains – cowpea, maize, and soybean), pest management, and crop-based farming systems for smallholder farmers of sub-Saharan Africa.

Some work on processing quality is carried out by the centers, but very little work on grain storage and other postharvest technologies. While germ plasm development is still the main focus, there has been an increased involvement in recent years in natural resource management, farming systems research, and in understanding social, policy, and economic constraints. There is a level of tension within the CGIAR system as a whole on the appropriate balance of such activities; given that there have been few additional funding resources in real terms over the last decade.

Major Public Sector (Government and University) Grain Science Organizations

Asia Pacific

There are three main public sector providers in grains research in Australia – state departments, Commonwealth Scientific and Industrial Research Organization (CSIRO – national government organization), and universities. State departments are the main research providers. The national government department – Agriculture, Fisheries, and Forestry Australia (AFFA) – does not conduct laboratory or field research in agriculture. In the last 10–15 years, there has been a shift in emphasis of many state departments from an overwhelming emphasis on production agriculture toward sustainable production. Nonetheless, the states remain particularly strong in crop improvement and agronomy, and in soil science and farming systems research. A summary is provided in Table 1. An increasing proportion of extension services, formerly provided by the states, are now provided to farmers on a commercial basis by these departments or by the private sector.

Some of the divisions of the CSIRO conduct research in grains production and processing, including:

- Plant industry – genomics of grains including wheat and rice; barley genetic engineering; wheat starch composition; breeding of winter wheats and oilseeds; physiology, agronomy, and adaptation of cereal crops, soybean, mung bean; sustainable crop-pasture systems; Mediterranean cropping systems; cereal chemistry and rapid testing methods.
- Entomology – Stored Grain Research Laboratory.

Table 1 Some Australian state government departments undertaking significant grains research

Department (website)	*Grains research emphasis*
NSW Agriculture (www.agric.nsw.gov.au)	Bread, biscuit, and durum wheat breeding; malting barley breeding; oat breeding; rice breeding, nutrition, pests, and quality assessment
	Cereal, canola, and pulse agronomy and disease management; crop-pasture rotations
	Chickpea, faba bean, field peas, canola, lupins with enhanced yield, and disease resistance
Dept. of Primary Industries, Agriculture, Victoria (www.nre.vic.gov.au)	Dryland cropping; sustainable cereal/pasture-based farming systems
	Cereal molecular marker development
	Milling wheat, malting barley, pulse and oilseed brassica breeding
	Pulse agronomy, pathology, and processing
Queensland Dept. of Primary Industries (www.dpi.qld.gov.au)	Wheat and oat breeding and quality assessment
	Malting barley breeding and barley biochemistry
	Tropical maize improvement; sorghum breeding and pest management
	Soybean and peanut breeding and agronomy
	Subtropical grain farming systems; new grain crops (pearl millet, guar, and adzuki beans)
	Integration of cropping systems and climate models
	Grain storage technologies
South Australian R&D Institute (SARDI) (www.sardi.sa.gov.au)	Bread and durum wheat, triticale, oat and malting barley improvement
	Chickpea and lentil improvement
	Biotechnology in cereal crop improvement
	Cereal chemistry and quality assessment
	Cereal, pulse, and oilseed pathology and disease diagnostics
	Soil-borne root diseases and abiotic constraints to productivity
	Agronomy, tillage practices, climate risk-management
Dept. of Agriculture, Western Australia (www.agric.wa.gov.au)	Wheat and barley breeding and agronomy for Mediterranean environments
	Cereal–pasture farming systems
	Canola and field pea
	Grain storage and protection
	Cereal chemistry and Asian products
	Pulse pathology
Dept. of Primary Ind., Water and Environment, Tasmania (www.dpiwe.tas.gov.au)	Cool temperate cereal breeding and selection
	Brassica oilseed variety assessment
	Assessment of soybean and broadbean varieties
Dept. of Business, Indy and Resource Development, Northern Territory (www.nt.gov.au)	Agronomy of irrigated maize, peanuts, sesame, and rice production

- Food Science Australia – extrusion cooking; mycotoxin contaminants.
- Land and water – sustainable use of soil and water resources in grain cropping.
- Sustainable ecosystems – rodent pests of cereal crops; predictive understanding of biophysical and ecological processes.

BRI Australia Ltd. is an independent nongovernment grains research organization. Areas of research expertise include milling, near infrared reflectance technology, baking science and technology, and Asian wheat foods (noodles and steamed breads). AWB Ltd.'s (formerly The Australian Wheat Board) R&D laboratory, Agrifood Ltd., has an emphasis on testing services, although some research on nutrition, milling, and wheat products is carried out.

There are ~20 tertiary institutions that teach and research aspects of agriculture, horticulture, forestry, fisheries, and natural resource management. Relevant grains research is carried out at several universities. This includes:

- University of Adelaide – bread and durum wheat and barley breeding, molecular markers, cereal root diseases, cereal pathology, biotechnology, weed management, malting, and brewing biochemistry;
- University of Sydney – breeding for rust resistance in barley and wheat; wheat, oat, rye breeding for processing quality; cereal diseases; cereal genomics; precision agriculture; soil science; crop modeling;
- University of Melbourne, through its Joint Centre for Crop Innovation associated with the School of Land and Food emphasizes research to underpin the sustainability of temperate grain crop production, with emphasis on variety development,

agronomy and farming systems, and protection of natural resources;
- University of New England – agronomy and soil science, plant nutrition, crop protection, weed science, integrated pest management;
- University of Queensland – production and post-harvest handling of cereals, grain legumes and oil-seeds; weed management; plant protection; molecular biology; sustainable grains production systems; and
- University of Western Australia – grain crop science and molecular genetics.

Smaller university research efforts are based at:

- Charles Sturt University – agronomy, irrigation, fertilizer management of grain crops, plant pathology;
- Curtin University Muresk Institute – agronomy, precision agriculture;
- Murdoch University – molecular markers for barley and wheat, grain legume genome mapping, transgenics diseases and viruses;
- Southern Cross University – cereal genotyping technology: cereal processing and health benefits;
- University of New South Wales –grain storage engineering;
- University of South Australia – agricultural machinery research and design;
- University of Southern Queensland – plant-pathogen interactions, cereal genetic engineering, marker-assisted breeding, canola breeding; and
- University of Tasmania –cereals, grain legumes and oilseeds as break and rotation crops.

Over the last 10–15 years, there has been a significantly increased emphasis on establishment of more formal links between research organizations. This has been driven to a significant extent by the advent of the Cooperative Research Centres (CRCs) program and encouragement by funders such as the Grains R&D Corporations (RDCs). A special feature of the Australian research landscape are the CRCs. This program, funded by the government, was launched in 1990 to strengthen collaborative linkages between industry, research organizations, universities, and government agencies. CRCs cover all areas of science and technology, but several of the centers relate to grain production and processing. As of January 2003, these include:

- CRC for Value-Added Wheat, following on from the Quality Wheat CRC, focuses on the development of wheat varieties, agronomic management, new approaches for the assessment of wheat quality, and improved wheat processing quality;
- CRC for Innovative Grain Food Products emphasizes high-value functional grain foods;
- The CRC for Sustainable Rice Production emphasizes increased production efficiency, development of value-added products, and improved management of soil and water resources;
- The CRC for Molecular Plant Breeding emphasizes the identification and utilization of molecular markers in cereal and pasture grass breeding;
- The CRC for Weed Management Systems emphasizes nonchemical management of weeds, including in cereal-based farming systems;
- Centre for Legumes in Mediterranean Agriculture (CLIMA) emphasizes research on the role of grain and annual pasture legumes in the Mediterranean climate of Western Australia. Research strengths include breeding, germ plasm assessment, pests and diseases, molecular biology, and crop physiology of legumes.

The Rural RDCs, of which the Grains RDC is the relevant one for grains research, facilitate and manage funding for research and assist in communicating results. They are generally funded on the basis of the government, matching the industry R&D levies dollar-for-dollar up to a maximum of 0.5% of the industry's gross value of production (GVP). Until the early to mid-1990s, most RDCs saw themselves as "reactive" funding bodies that selected a limited number of projects for funding from a larger number of competitive proposals. Managers from most RDCs now play a much greater role in determining research priorities in consultation with particular industries, and are being involved in project design and negotiating research partnerships. In grains, funding mechanisms have provided strong encouragement for different laboratories working on particular diseases and breeding targets within a given agro-ecological zone to collaborate more closely and formally.

Much of Australia's plant breeding is still done in the public sector, although, in many cases private sector seed companies now license the varieties developed from the research and distribute and market the seed to farmers. Increased commercialization of plant breeding and development of national breeding networks for major grains are recent developments and have reduced research duplication.

The main New Zealand organization undertaking grains research is the NZ Institute of Crop and Food Research. It is one of nine government-owned research institutes. It has a strong emphasis on grain crop improvement as well as basic cereal science and baking technology. Universities with research

interests in grains include Massey University (Palmerston North) with a research emphasis on food science and engineering. Lincoln University (Christchurch) carried out research on grain foods composition, crop agronomy, seed science and technology, and some biotechnology. Although, wheat is one of the major cereals, the growing environment is very different from that in Australia, requiring rather different varietal characteristics.

In Japan, much of the grains research is carried out in institutes managed under the Agriculture, Forestry, and Fisheries Research Council of the Ministry. Crops (including grains) research is carried out in a series of regional institutes in Hokkaido, Tohoku, Hokuriku, Chugoku, Shikoku, and Kyushu, and grains nutrition at the National Food Research Institute in Tsukuba. Major universities with agriculture faculties include Tokyo University of Agriculture and Technology, Tohoku, Kyoto, Kyushu, Hokkaido, Kagoshima, Yamaguchi, Tottori, and Nagoya. Several universities carry out research in grains processing.

The Korean Rural Development Administration of the Ministry of Agriculture and Forestry has a series of national research institutes, including the National Crops Research Institute, National Institute of Agricultural Science and Technology (with relevant work on crop protection and agro-ecology), National Institute of Agricultural Biotechnology, National Rural Nutrition Institute, and nine provincial agricultural and extension institutes. Korea Food Research Institute and the Korea Research Institute of Bioscience and Biotechnology function under the Ministry of Science and Technology. Grains research is strongly rice-focused, but with an increasing environmental protection and biotechnology emphasis.

China has one of the largest NARS in the world, and in recent years the government has placed a high priority on developing research capacity and infrastructure. Because of the large range of production environments, research on both temperate and tropical grains is important, and some institutes undertake pioneering grains research, for example in the development of high-yielding rice varieties, rice functional genomics, and transgenic crops. In recent years, the Chinese government has been making investments in R&D that are huge by any standards; the physical infrastructure and equipment have significantly improved, and there has been a move to retain or attract back eminent scientists. There is an increasing shift in emphasis in China from research aimed at increasing grain production to increasing quality and ensuring that production is environmentally sustainable, especially in view of the increasing pressure on water resources for agriculture in China.

Grains research is carried out in five main types of organizations. The Chinese Academy of Agricultural Sciences (CAAS) governed by the Ministry of Agriculture is the national academy with the largest number of grains research projects. It can also confer postgraduate degrees. Of its 38 institutes, 16 carry out grains science research, including the Institute of Crop Germplasm Resources, Beijing; Institute of Crop Breeding and Cultivation, Beijing; Institute of Plant Protection, Beijing; Institute of Biological Control, Beijing; Biotechnology Research Center, Beijing; Institute of Feed Research, Beijing; Institute of Soils and Fertilizers, Beijing; Institute of Agricultural Mechanisation, Nanjing; China National Rice Research Institute, Hangzhou; Agro-Environment Protection Institute, Tianjing; Institute of Oil Crops, Wuhan. Main thrusts are crop breeding, germ plasm conservation, development of biotechnology tools, natural resource management and protection (with a recent emphasis on water-saving agriculture for arid and semiarid regions), integrated pest management and agricultural mechanization to improve efficiency.

The Chinese Academy of Sciences (CAS) also carries out some research relating to grains, at the Institute of Botany and Institute of Genetics (Beijing, basic plant biology and biotechnology), Institute of Zoology (Beijing, pest management), Institute for Soil Research (Nanjing), National Centre for Genetic Research, Shanghai (rice genomics), Chengdu Institute of Biology (cereal breeding); Institute of Soil and Water Conservation, Yangling (agronomy), NW Plateau Institute of Biology, Qinghai (crop assessment), and Shijiazhuang Institute of Agricultural Modernization, Hebei (farming systems for the North China plain) among others.

Provincial academies of agricultural science are increasing in resources. Those with strengths in strategic or applied grains include Jiangsu, Sichuan, Guangdong, Fujian, Henan (for wheat), Shandong, Liaoning, and Gansu. The Beijing Food Research Institute carries out some cereal-processing research, while the State Administration of Grain Reserves also carries out grain-storage research, including through the Grain Storage Research Institute in Chengdu. The four strongest universities in terms of agricultural science are China Agricultural University (Beijing), Nanjing Agricultural University, Zhejiang University, and Huazhong Agricultural University. Other agricultural universities carrying out grains research are South China Agricultural University (Guangzhou), Shenyang Agricultural University, Central China Agricultural University (Wuhan), South-West Agricultural University (Chongqing) and North-West Agricultural University (Yangling). The

botany department at the University of Hong Kong carries out basic research on rice grain structure, maize breeding and processing research on wheat, oats, and soybeans.

India has one of the largest NARS in the world, and a traditional strength in grains sciences. ICAR has almost 30 000 staff, including 7000 research scientists. Most grains research is done within the Indian Council for Agricultural Research Institutes. Of its 46 Central Research Institutes, most of the grains research institutes are within the Crop Science Division. Major thrusts include development of grain varieties resistant/tolerant to a range of abiotic and biotic stresses, hybrid technology, application of molecular techniques, plant genetic resources conservation, and farming systems research. The main ICAR institutes carrying out grains research include:

- Indian Agricultural Research Institute, New Delhi (emphasis on more strategic research);
- Central Rice Research Institute, Cuttack, Orissa;
- Indian Institute of Pulses Research, Kanpur, Uttar Pradesh;
- National Bureau of Plant Genetic Resources, New Delhi;
- National Research Centre for Groundnut, Junagarh, Gujarat;
- National Research Centre for Rapeseed Mustard, Bharatpur, Rajasthan;
- National Research Centre on Sorghum, Hyderabad, Andra Pradesh;
- National Research Centre on Soybean, Indore, Madhya Pradesh;
- National Centre for Integrated Pest Management, New Delhi;
- National Research Centre for DNA fingerprinting, New Delhi; and
- National Research Centre on Plant Biotechnology, New Delhi.

Several smaller project directorates covering biological control, oilseeds, rice, wheat, and maize. In addition, All-India Coordinated Research projects attempt to link institutes; current coordinated projects cover all major (and most minor) cereal, oilseed, and pulse crops, as well as specific pests such as white grubs and rodents. An even bigger resource is the 29 State Agricultural Universities (SAUs), which fall under the ICAR. They employ almost 26 000 scientists in teaching, research, and extension roles. Some of the SAUs with strong grains research programs include Acharya NG Ranga AU (Andhra Pradesh), CCS Haryana AU, GB Pant AU (Uttar Pradesh), Punjab Agricultural University, and Tamil Nadu AU. The Council for Scientific and Industrial Research (CSIR) has a set of national institutes in different areas of science and technology. The Central Food Technological Research Institute (CFTRI, Mysore) has a department which researches cereal (especially wheat) milling, baking, and biochemistry.

The major Indonesian government agricultural research and development agency is Indonesian Agency for Agricultural Research and Development (IAARD). Research institutes working on grains within the Central Research Institute for Food Crops are the Rice Research Institute, Sukamandi, Java; Research Institute for Maize and Other Cereals, Makassar, Sulawesi; Research Institute for Legume and Tuber Crops, Malang, Java and a research station for (rice) tungro disease. New research institutes for biotechnology and genetic resources and for postharvest technology have recently been established. Adaptive research is carried out by Assessment Institutes for Agricultural technology (under IAARD, but located in each province). Major agricultural universities include Bogor Agricultural University (IPB), Gadjah Mada University (Yogyakarta), Hassanuddin University (Makassar), University of Mataram (Lombok), and Universitas Sam Ratulangi (Manado).

Under the Philippines Department of Agriculture (DA), there is a national rice research center (PhilRice in Munoz, Luzon), addressing both research and technology dissemination, and the Bureaus of Plant Industry, Soil and Water Management and Postharvest Research and Extension. The last of these is based at Munoz (on the Central Luzon State University campus) and has two main research emphasis – grain storage and processing of high-value crops such as potato, cashew, coffee, and beans. There are also Regional Integrated Agricultural Research Centres – there is one organization in each of the 15 Regions, but some have 2–3 research stations, and several focus on grain crops. The strongest university in grains research is the University of Philippines at Los Banos, which has specialized institutes of plant breeding and of farming systems research.

There are also a number of universities in regions with strengths in agriculture, and the universities have a far greater share of research capacity than DA. These include Benguet, Central Luzon State, Visayas State College of Agriculture, Don Mariano Marcos State University, Central Mindanao, and Southern Mindanao. There are also several others with some strengths in agriculture (Mindanao State, Bicol, Central Visayas State). Some of the universities have regional research and development centers involving the National departments of Agriculture and of Environment and Natural Resources, and some of

the state universities also have quite good extension/outreach systems.

The Thailand Department of Agriculture (DOA) of the Ministry of Agricultural and Cooperatives is responsible for crop research while the Department of Agricultural Extension (DOAE) is responsible for transfer of technology to farmers. While there are experiment stations in every region of the country, most research is carried out in Bangkok. DOA has technical divisions covering agricultural chemistry, agricultural engineering, plant pathology and microbiology, entomology and zoology, soil science, botany, and weed science, and agricultural toxic substances (pesticides), and specialist rice and field crops institutes (there is reasonable research capacity in maize and legumes research). The Land Development Department conducts research in relation to land improvement and soil and water conservation. Grains postharvest technology is carried out within the Thailand Institute of Scientific and Technological Research (TISTR) in Bangkok. One of the three research centers with National Science and Technology Development Agency is Genetic Engineering and Biotechnology (BIOTECH). Kasetsart in Bangkok, Khon Kaen, Chiang Mai University, Prince of Songkla University (Hat Yai), and King Mongkut's Institute of Technology in Bangkok are all involved in grains research, the latter having a special focus on grains postharvest technology.

In Malaysia, the Rice and Industrial Crops Research Centre of the Malaysian Agricultural Research and Development Institute (MARDI) researches rice, maize, and groundnuts as well as several nongrain crops. The most relevant activity is development of high-quality rice varieties with disease resistance and accompanying agronomy. The food technology research centre does work on the development of rice-based snacks and other food products. The major university carrying out grains science research is University Putra Malaysia.

The Pakistan Agricultural Research Council, PARC coordinates much of the government agricultural R&D effort. The main institute, the National Agricultural Research Centre at Islamabad has several sections relevant to grains research, covering soil fertility, sorghum and millet, farm machinery, water resources, agricultural biotechnology, vertebrate pests, crop diseases, crop production, land resources, plant genetic resources, and seed sciences. There is a separate tropical agricultural research center at Karachi, four arid zone research centers in different regions of Pakistan. There are several agricultural universities in Pakistan which carry out grains research, the largest being the Pakistan Agricultural University at Faisalabad. Sindh Agricultural University, the University of Arid Agriculture (Rawalpindi), the Northwest Frontier Agricultural University (Peshawar) are all smaller, but with a similar range of activities. The Ministry of Science and Technology manages the Pakistan Council of Scientific and Industrial Research, which carries out grains postharvest research. There is also a separate National Institute for Biotechnology and Genetic Engineering (Faisalabad).

Most grains research in Vietnam is conducted under the Ministry of Agriculture and Rural Development (MARD). Other relevant ministries are Education and Training (university sector); Science, Technology and Environment (MOSTE), which has some excellent crop biotechnology and plant protection research facilities and the Ministry of Industry (which has an Oil Plant Research Institute – with the mandate for peanut, soybean, sunflower, and sesame). While most institutes are located in either Hanoi or Ho Chi Minh city, many maintain "research centers" in more remote locations.

The key MARD institutes in grains science are the National Institute for Plant Protection, National Institute for Soils and Fertilizers, Post-Harvest Technology Institute, Vietnam Agricultural Science Institute, Institute of Agricultural Genetics, and the Cu Long Delta Rice Research Institute. The Department of Plant Protection of MARD is also becoming an important applied research organization. The main universities with research interests in grain science include Hanoi Agricultural University, Hanoi University of Science (also known as Hanoi College of Sciences), University of Agriculture and Forestry (in Ho Chi Minh city, the university is now known as Nong lam University), and Can Tho University.

Central and South America

Brazil has a well-developed NARS, with many centers falling under EMBRAPA (Empresa Brasilera de Pesquisa Agropecuaria – Brazil Agricultural Research Corporation), a specialized science agency of the Agriculture Ministry. Brazil has the largest NARS of any Central or South American country, followed by Mexico; Brazil also has an advanced university system. There are separate EMBRAPA institutes relating to genetic resources and biotechnology (CENARGEN), rice and beans (CNPAF), corn and sorghum (CNPMS), soils (CNPS), soybean (CNPSO), wheat (CNPT), temperate climate agricultural research (CPACT, Temperate rice), and agro-industrial food technology (CTAA). Many of the Brazilian states have state "research corporations" that carry out grain crop assessment. There are also nonprofit centers – wheat experimentation and research (FUNDACEP)

and the Rice Institute of the Rio Grande (IRGA). Several universities carry out grains research – the Federal Universities of Goias, Lavras, Paraiba, Pelotas, Rio Grande do Sul, Rural do Rio de Janeiro, Santa Catarina, Sao Carlos, Santa Maria, Vicosa, and Brasilia as well as several state universities – Santa Catarina State, Paulista, Campinas, Sul de Santa, and Sao Paulo. Some Brazilian companies, such as Agroceres, Duraflora, Mogiana, and Braskalb carry out breeding and agronomy research to support seed distribution businesses.

The Argentine Government Instituto Nacional de Technologia Agropecuaria (INTA) is under the Agriculture Ministry, but there are a large number of programs and centers relevant to grains research under CONICET, which is under the Culture and Education Ministry. This includes centers for maize (CIG), plant protection (CIPEN), rice and biotechnology (IMBIV), postharvest technology (INSIBIO and INTECH), and semiarid crops (CERZOS). Several national universities have agronomy science faculties – Buenos Aires, Buenos Aires Province, Catamarca, Comahue, Cordoba, Cuyo, Entre Rios, Jujuy, La Pampa, La Plata, Litoral, Lomas de Zamora, Mar del Plata, Noredeste, Rio Cuarto, Rosario, Santiago del Estero, de Sur, de Salta, Tucuman, and de Formosa.

The Chilean Ministry of Agriculture has an Instituto de Investigaciones Agropecuarias (INIA) which undertakes some grains research. There are also agronomy departments at several universities – Austral, Conception, Frontera, Serena, Magallanes, Talca, Tarapaca and Universidad de Chile, Universidada Iberomerica de Ciencas as well as the Catholic universities – Temuco, Valparaiso, and Maule. In Colombia, the main government crops research agency is CORPOICA; under the Asociacion Nacional de Acuicultores (ACUANAL), there are research groups working on wheat, barley, maize, sorghum, and rice. Apart from the campuses of the national university, other universities with agronomy faculties include Cordoba and Tolima. The main research agency in the Ecuador agriculture ministry is INIAP (Instituto Nacional Autonomo de Investigaciones Agropecuarias); universities in most regional centers have small agronomy departments.

In addition, Roseboom and co-workers have provided information on grains research in the Carribean.

Africa and the Middle East

South Africa has the best-developed NARS of the African countries, and reasonable research capacity in maize (the main grain crop), sorghum, and some experience in wheat and barley. The Agricultural Research Council is the main agricultural research structure, and has a series of research institutes, several carrying out grains research – these include the Institutes for Agricultural Engineering, Range and Forage, Industrial Crops, Plant Protection, Grain Crops Institute and Soil, Climate, and Water. The nine provincial departments also carry out selection and agronomy research, including those in Eastern Cape (Dohne), Free State (Glen), Natal (Cedara), and Elsenburg. There are some well-resourced grains research programs at the University of Pretoria, Natal, Free State, and Stellenbosch. Traditionally Black universities are increasing in strength, and several emphasize agriculture, including University of Fort Hare, University of the North and Venda. In the 1990s, there has been a significant shift in research emphasis in South Africa to accommodate the needs of the wider population, rather than just white commercial agriculture, to include emerging farmers and subsistence farmers in former homelands. In Zimbabwe, most crops research is carried out by the Department of Research and Specialist services in the Ministry of Lands, Agriculture and Water Development, with the University of Zimbabwe maintaining reasonable strength. Some of the grains IARCs, such as CIMMYT and ICRISAT have maintained successful in-country programs in Zimbabwe, too.

The Kenya Agricultural Research Institute (KARI) is comparatively strong in crops and livestock; overall the Kenyan government agricultural research system is the second strongest in Africa, next to that of the Republic of South Africa. In the grains area, mandate crops include cereals (wheat, maize, sorghum, millets, and rice) and grain legumes (dry beans, cowpeas, mung beans, pigeon pea, chickpeas, and Dolichos) with efforts ranging from plant breeding for adaptation to different agro-ecological zones and stress resistances, agronomy, postharvest technology, and cooking quality. Almost all Kenyan grain production is rain-fed. The maize breeding and seed distribution program has probably been the most extensive. The breeding and postharvest research is backed up by a soil and water management research program. Some grains research is carried out at various universities (Egerton, Moi, University of Eastern Africa, and University of Nairobi). The Ethiopian Agricultural Research Organization (EARO) has national centers emphasizing maize, plant protection, soils, and agricultural mechanization as well as a number of centers in regional areas. Crops research is carried out at Alemaya University and Mekele University. In Nigeria, the Ministry of Agriculture has a series of research institutes – National Cereals Research Institute, Lake Chad Research Institute, and the Institute for Agricultural research. Postharvest technology

research is carried out under the Ministry of Industry at the National Stored Products Research Institute. Universities with relevant research programs include the University of Ibadan, University of Nigeria, Obafemi Awolowo, and Maiduguri. In Zambia, the Soils and Crops Research Branch of the Ministry of Agriculture, Food and Fisheries and the University of Zambia are the main grains research providers. In Tanzania, it is the Directorate of Research and Development of the Ministry of Agriculture and Food Security, while in Ghana, the Crops Research Institute of the Council for Scientific and Industrial Research, along with the University of Ghana and the University of Science and Technology are the crops research providers. In Sudan, the major grains research organizations are the Agricultural Research Corporation (within the Ministry of Agriculture and Forestry) and the Universities of Khartoum and Gezira.

The Israeli NARS is reasonably well resourced. Within the Agricultural Research Organization several institutes are relevant to grains research, including the Institutes for Field and Garden Crops (IFGC); Plant Protection; and Soil, Water and Environmental Services. The IFGC has a particular emphasis on wheat breeding to overcome drought, disease stress and heat tolerance in wheat and sorghum. There are also peanut breeding and rhizobiology programs. Universities carrying out grains research include the Technicon, Israel Institute of Technology (Haifa), and the Ben-Gurion University of Negev. Egypt also has a very large government agricultural research system, within the Agricultural Research Center (ARC), within the Ministry of Agriculture and Land Reclamation. In ARC, there are separate institutes for field crops, plant protection, plant pathology, food technology (bread and pasta research), agricultural genetic engineering, and soil, water, and environment research. There are programs on wheat, barley, maize, rice, sorghum, legumes, and oil crops. Universities with agriculture faculties include Alexandria, Cairo, Ain Shams, Al Azhar, Suez Canal, Zagagig, Assiut, Mansoura, Minia, Menoufa, Tanta, and South Valley. Further information on grains research in other West Asia and North African countries is provided in Casas *et al*. (1999).

CGIAR

F J B Reifschneider and S Hussain, CGIAR, Washington, DC, USA

Introduction

Agriculture has played a central role in human affairs since the Neolithic revolution, when humans first made the transition from food gathering to a food-producing society.

At the dawn of the twenty-first century, agriculture's important role in human affairs has not diminished. (In this section, the term "agriculture" is used *sensu latu*, i.e., comprising crop and animal husbandry, fisheries, agro-forestry, and forestry.) There is growing international consensus that agricultural development remains central to economic advance, environmental protection, and social well-being. Agriculture is closely linked to the development agenda, including the Millennium Development Goals (MDGs) and goals of the 2002 "World Food Summit: Five Years Later" and the "World Summit on Sustainable Development."

Current and Future Challenges

Agriculture's links to the broad development agenda are evident from the following:

- poverty affects three billion people, of which 1.2 billion live in deep deprivation earning less than $1 per day;

- most of the world's poor people depend directly or indirectly on agriculture for their livelihoods;
- 815 million people in the world are undernourished;
- earth's ecosystems are under stress: 40–50% of land has already been irreversibly transformed or degraded by human actions and agricultural activities;
- biodiversity is being lost at unprecedented rates: one-third of terrestrial biodiversity, accounting for 1.4% of the Earth's surface, is in vulnerable "hot spots" and threatened with complete loss in the event of natural disasters or further human encroachment;
- most of the world's water is used for irrigation, and agriculture frequently accounts for 70% of freshwater withdrawals; and
- agricultural activities are one of the leading causes of climate change, contributing $\sim$20% of all greenhouse gases.

Globally, the agricultural sector is set to face pressing challenges in the future.

- World population is expected to reach nine billion by 2050.
- Over the same time frame, demand for food is set to more than double, with most of the increased demand coming from developing countries.
- Erosion, salinization, compaction, and other forms of soil degradation affect 30% of the world's irrigated lands, 40% of rainfed agricultural lands, and 70% of rangelands.
- Most of the world's freshwater is used for irrigation; it takes 3000–5000 l of water to produce 1 kg of rice; water use is expected to increase by 50% by the 2030s.
- Arable land per person in developing countries has shrunk from 0.32 ha in 1961–63 to 0.21 ha in 1997–99 and is expected to drop to 0.16 ha by 2030.
- Cereal productivity growth increases (i.e., rises in cereal yields per ha) are decelerating, and in developing countries these declined from 2.2% per year in 1967–82 to 1.5% per year during the 1980s and early 1990s
- Forty percent of plant productivity in Africa and Asia is lost to insect pests and pathogens, and
- Earth's average surface temperature could rise by as much as 1.4–5.8°C over the next 100 years, increasing thermal stress, negatively affecting agricultural production in developing countries.

Given these challenges, science-based agricultural development will continue to be an important method for promoting economic growth and addressing current and future food, poverty, and environmental challenges.

Plants, Food, and People: History of Concern

Hunger has been a constant companion of the human family, and concern about hunger and the world's ability to feed growing populations has been a recurring theme throughout history.

In the modern epoch, the Irish famine, and the famines of the twentieth century in Bengal (1943–44), Bangladesh (1974–75), China (1959–61), Holland (1944–45), and during the 1970s–80s in large parts of Africa (Ethiopia, Sudan, Mozambique, Nigeria, Niger, Somalia, and Zaire) caused millions of deaths. Famines, the most severe form of deprivation, can result from breakdowns in food grain production and distribution, and from a restricted flow of income with which people buy food. Shocks in the agricultural sector (plant disease as in the case of Irish famine, extreme weather events such as droughts and floods) and human-induced conflicts and civil wars can all trigger famines.

In the continuing debate on food adequacy, one of the early alarms was sounded by Thomas Robert Malthus in 1798, with the publication of *An Essay on the Principle of Population as it Affects the Future Improvement of Society*. His hypothesis was simple: left unchecked, the world would exhaust its food supplies because population grows geometrically while agricultural production grows arithmetically.

The 1960s marked a period when deep-rooted pessimism about food availability surfaced anew. In the 1990s, the Worldwatch Institute warned that due to population pressures and food grain shortages, China would resort to massive grain imports, triggering unprecedented increases in world food prices and causing starvation in the rest of the world.

In a fortunate coming together of human ingenuity and grain science, food and environmental scientists working with farmers successfully averted the worst Malthusian specter by ensuring abundant agricultural yield. The story of wheat improvement in England is compelling. It took nearly 1000 years for wheat yields to increase from 0.5 to 2 metric tons per hectare (mt ha^{-1}), but only 40 years to climb from 2 to 6 mt ha^{-1}, illustrating the ability of modern grain science to increase agricultural productivity.

Mobilizing Grain Science for Development

The Consultative Group on International Agricultural Research (CGIAR) was established in 1971.

A group led by The Rockefeller Foundation, Ford Foundation, Food and Agriculture Organization, The World Bank, and others created the CGIAR.

The founding objective was based on a profound belief in the ability of science, especially grain science, to increase the world's "pile of rice," i.e., food in low-income countries facing severe food scarcity. The central idea of mobilizing grain science internationally to meet food and development needs, within a public goods framework, was novel.

The CGIAR is best known for the "Green Revolution," a term coined by William S. Gaud and used to refer to the set of agricultural innovations (new high-yielding varieties (HYVs) of wheat, rice, and maize, increased investments in irrigation, easy availability of farm inputs such as fertilizers and pesticides, improved grain distribution, and food policies in developing countries) that helped boost grain yields and incomes of farmers in poor, agrarian economies.

The Green Revolution transformed agriculture in developing countries especially in India, Mexico, Pakistan, and Philippines.

Cereal crop yields and food production more than doubled between 1960 and 1985. The new HYVs of rice, wheat, and maize increased daily calorie supply in developing countries by 25%, from under 2000 calories per person in the early 1960s to 2500 calories per person in 1990s. The evidence is incontrovertible: without the productivity growth in basic food crops, the numbers of poor and hungry would have been far greater.

Critics of the Green Revolution have argued that the new crop technologies favored farmers in well-endowed areas, worsened pollution through excessive use of fertilizers and pesticides, threatened biodiversity, promoted monocultures, and required higher input costs from impoverished farmers.

While a comprehensive discussion of these issues is beyond the scope of this article, subsequent studies and analyses have increased understanding about the effects of the new technologies. A range of subsequent policy interventions (e.g., increased credit, improved marketing and seed distribution facilities, land reforms, and strengthened emphasis on pesticide safety, and others) have helped poor farmers to benefit from Green Revolution technologies.

However, the benefits of the Green Revolution were spread unevenly and bypassed Africa. Gordon Conway has called for a "Doubly Green Revolution" focused on the research and development needs of Sub-Saharan Africa. On an average, crop yields in Africa are one-third of those achieved by Asian farmers. Less than 4% of Africa's arable land is irrigated. There is enormous potential for growth-led productivity in Sub-Saharan Africa where agriculture provides 70% of employment, 40% of exports, and one-third of gross domestic product.

Evolving Research Agenda, Steadfast Focus on Fundamentals

CGIAR's mission is "to achieve sustainable food security and reduce poverty in developing countries through scientific research and research-related activities in the fields of agriculture, forestry, fisheries, policy, and natural resources management." CGIAR achieves its mission through the work of 16 International Agricultural Research Centers (IARCs) that work with national agricultural research systems, the private sector, and civil society (see Figure 1). The IARCs are autonomous institutions, linked by a common commitment to promoting agricultural development in developing countries; 13 IARCs are headquartered in developing countries.

CGIAR's mission has evolved over time (see Figure 2), and this is reflected in its structure. When the CGIAR was founded, four IARCs (International Center for Tropical Agriculture (CIAT), International Maize and Wheat Improvement Center (CIMMYT), International Institute of Tropical Agriculture (IITA), and International Rice Research Institute (IRRI)) were brought under its umbrella. Subsequently, new IARCs were established to pioneer improvements in key food crops (legumes, roots, tubers, and other cereals), livestock health, ecological regions (dry, semiarid, and tropical regions), and to conduct research on pressing issues involving agroforestry, forestry, water management, aquatic resources, food policies, and strengthening of national agricultural research systems.

The research programs undertaken at the 16 IARCs are organized around five focus areas:

- increasing productivity (of crops, livestock, fisheries, forestry, and the natural resource base);
- strengthening national systems (through joint research, policy support, training, and knowledge-sharing);
- protecting the environment (by developing new technologies that make more prudent use of land, water, and nutrients and help reduce agriculture's adverse impacts on ecosystems);
- saving biodiversity (collecting, characterizing, and conserving genetic resources – the CGIAR holds in public trust one of the world's largest seed collections available to all); and
- improving policies (with a major impact on agriculture, food, health, the spread of new technologies and the management and conservation of natural resources).

CGIAR's research portfolio has evolved from the original focus on increasing productivity in individual critical food crops. The current approach

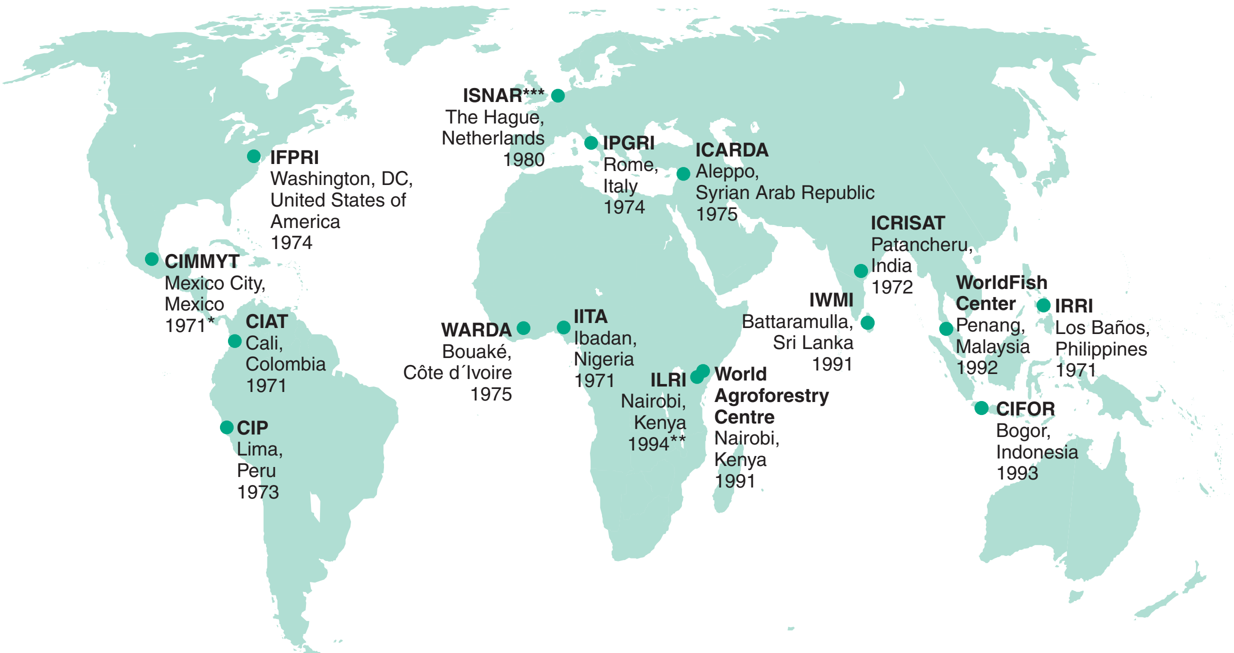

Figure 1 The CGIAR-supported network of International Agricultural Research Centers (IARCs). * Year when IARC joined CGIAR, ** The International Livestock Center for Africa (ILCA) and International Laboratory for Research on Animal Diseases (ILRAD) were merged to form ILRI, and *** In March 2004, ISNAR ceased operations and key elements of its mandate were brought under IFPRI governance in a program located in Addis Ababa.

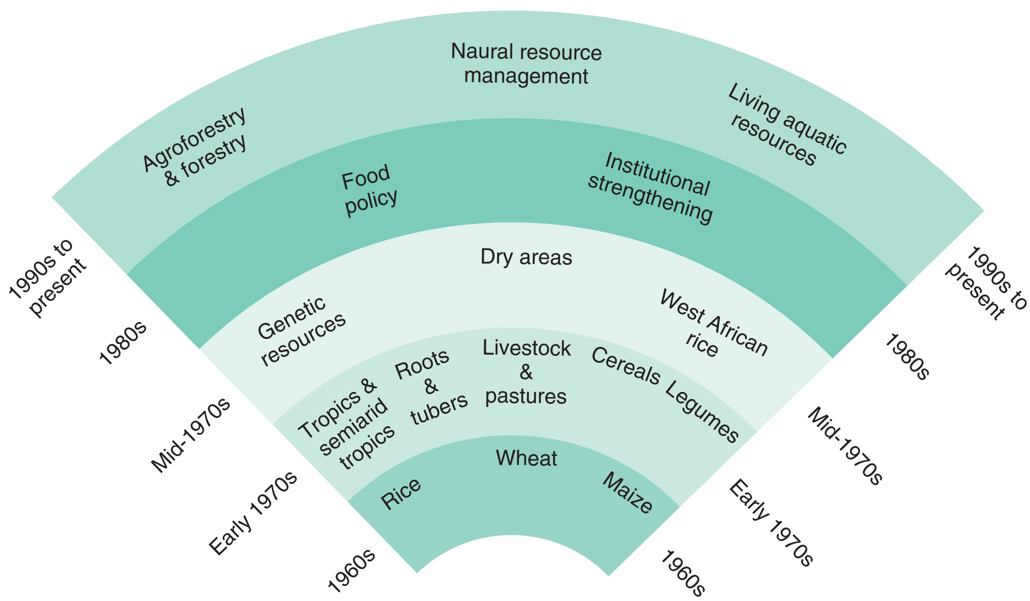

Figure 2 CGIAR's evolving research agenda.

recognizes that saving biodiversity, protecting the environment, improving food policies, and strengthening scientific capacities of developing countries through training and knowledge-sharing are all key components in the drive to enhance sustainable agricultural productivity. CGIAR's focus on the fundamentals remains as strong as ever: agricultural growth and increased farm productivity in developing countries creates wealth, reduces poverty, hunger, and protects the environment. In 2002, the CGIAR's

research investment of $337 million represented the single-largest effort in mobilizing science for agricultural development.

Ensuring the Quality of Science

CGIAR's founding fathers recognized the importance of independent scientific advice for ensuring the effectiveness and efficiency of research programs undertaken by the IARCs. This task was entrusted to a Technical Advisory Committee (TAC), an independent body charged with identifying research priorities and monitoring the relevance and quality of science. In 2004, as part of the ongoing reforms a new "Science Council" was established to strengthen the quality of CGIAR science. By arrangement, the Science Council operates from the Rome-based headquarters of the Food and Agriculture Organization (FAO).

Grain Science and the CGIAR

Improving the sustainable productivity of food grains is a major objective of CGIAR research. Grains are broadly defined as cereals belonging to the monocot family (barley, maize, millets, rice, sorghum, wheat, and other coarse grains) excluding legumes and pulses that are included in the dicot family. Nine of the 16 IARCs have specific crop improvement mandates (see Table 1). For the purposes of this paper, only eight IARCs have crop improvement mandates that correspond to the definition of grains cited above, the exception being root and tuber crops, including potato. An additional qualification is in order. Even though the International Plant Genetic Resources Institute (IPGRI) does not have a plant breeding program, its mandate to serve as a world center for conserving plant genetic resources is germane to the focus of this article.

The following section provides a synopsis of CGIAR research impacts. Results are reported for the major food grains, ranked by importance. Space constraints preclude a more detailed overview, including the role and contributions of partners who have participated in and supported the research. The examples of impact are restricted to cereal grain crops as per the definition outlined above.

Impacts of CGIAR Grain Research – An Overview

Wheat

Wheat is a primary grain consumed by humans. The two most common kinds of wheat are bread wheat and durum wheat. World demand for wheat is surging, and global wheat consumption has doubled in the last 30 years to reach nearly 600 million ton (Mt) per year. World wheat production has remained steady at under 600 (Mt), with Australia, Canada, China, the European Union, India, Pakistan, Russia, Turkey, Ukraine, and the United States accounting for 80% of world wheat production.

Domesticated wheat and humans help each other in a relationship known as "mutualism" where humans first domesticated wheat but dependence on the grain also led to their domestication. The uniqueness of wheat in contrast to other cereals is that its kernel

Table 1 CGIAR Centers with crop improvement mandates

Center	*Year founded*	*Host country*	*Mandate crops*
International Center for Tropical Agriculture (CIAT)	1967	Colombia	Cassava, beans, rice, tropical forages
International Maize and Wheat Improvement Center (CIMMYT)	1966	Mexico	Maize, wheat (bread and durum wheat, triticale)
International Center for Agricultural Research in the Dry Areas (ICARDA)	1975	Syria	Barley, wheat (durum species), lentil, chickpea, faba bean, forage legumes
International Crops Research Institute for the Semi-Arid Tropics (ICRISAT)	1972	India	Sorghum, pearl millet, groundnut, chickpea, pigeonpea
International Institute of Tropical Agriculture (IITA)	1967	Nigeria	Cassava, yams, maize, soybean, cowpea
International Plant Genetic Resources Institute (IPGRI)[a]	1974	Italy	Genetic resources, cocoa, coconut/*Musa* species
International Rice Research Institute (IRRI)	1960	Philippines	Rice
International Potato Center (CIP)	1970	Peru	Potato, sweet potato
West Africa Rice Development Association (WARDA)	1975	Cote d'Ivoire	Rice

[a] The definition used to describe "grains" excludes potato and sweet potato, the mandate crops of the International Potato Center (CIP, founded in 1970), Lima, Peru. The work of IPGRI is included because of its global mandate to conserve plant genetic resources.

contains a gluten protein that makes it possible to produce a wide array of end products.

Global impacts CIMMYT has a global mandate for wheat improvement (bread and durum species).

In the late 1960s, about one-third of all wheat varieties in developing countries were CIMMYT crosses. By the 1990s, these numbers rose to about half from CIMMYT crosses and another quarter from varieties that had a CIMMYT parent. Worldwide, around 90% of all spring bread wheat releases had at least one CIMMYT ancestor; the percentage for durum wheat was even higher with nearly all spring durum wheat releases having a CIMMYT ancestor. In 1970, semi-dwarf wheat varieties were important only in Asia. By the 1990s, semi-dwarf wheat varieties covered 80% of world wheat area, with adoption rates of 90% and higher in Asia and Latin America. Wheat research has generated a total economic surplus of about $2.5 billion annually in developing countries, for total research costs that never exceeded $70 million annually.

Wheat improvement in West Asia and North Africa (WANA) ICARDA's wheat improvement research focuses on spring bread and durum wheats in the WANA region. Per capita bread wheat consumption is highest in the WANA region (185 kg per year), and rising. Wheat is generally consumed as flat (Arabic) or leavened (French) bread.

ICARDA grain scientists have made major advances in identifying new sources of resistance to abiotic stresses (drought, heat, and cold) and biotic stresses (rusts, Septoria diseases, and Hessian fly), in broadening genetic diversity, and in selecting for grain quality. In 2001, 15 international durum wheat nurseries representing over 800 lines and 10 000 segregating populations suitable for three WANA environments (continental, temperate, and highland) were distributed to national programs for testing. Efforts to broaden the genetic base of durum wheat (that is notably poor in genetic diversity) involved crossing improved dryland genotypes with WANA landraces, wild relatives, and bread wheat. Wild relatives of durum (*Triticum diccoides* and *T. monococcum*) were used to improve grain quality and resistance to leaf rust, leaf blotch, and yellow rust.

Rice

Rice is a member of the grass family (Gramineae) and belongs to the genus *Oryza*. *Oryza* includes 20 wild species and 2 cultivated species (cultigens): Asian rice (*Oryza sativa* L.) and African rice (*Oryza glaberrima*).

Rice farming dates back to the origins of agriculture. Rice cultivation is the world's most important economic activity, and rice is the staple food for the largest number of people on earth. Rice is a water-intensive crop, using two to three times more water than other cereals such as maize or wheat.

CGIAR's rice improvement mandate is fulfilled by IRRI, WARDA, and CIAT.

Global impacts IRRI began rice improvement in the 1960s, and the institute became the first IARC of the CGIAR. Expanding on the successes in wheat improvement, IRRI scientists successfully introduced semi-dwarfism into two *Indica* rice varieties (IR5 and IR8). The latter variety would lay the foundations of the Green Revolution in Asia.

IRRI has made substantial contributions towards improvement of rice varieties. Of the estimated 2040 rice varieties released over 40 years by national rice research systems of South and Southeast Asia, 219 were direct IRRI lines. Of the 2021 varieties, 31% had originated from one or more parents developed at IRRI. This number rises to 46% when the IRRI-developed varieties are included. In the 1970s, the release of IRRI-related varieties peaked at 60%, subsequently stabilizing at 40% of all varieties released.

The widespread diffusion of rice varieties signals a success story. The HYVs, in 1990s accounted for 75% in Asia and 40% in Latin America of the total area under rice cultivation. The increase in rice production has been enormous. Starting in the 1960s, world rice cultivation area expanded from 139–197 million hectares (Mha). Rice production more than doubled to 540 (Mt) in 2000, up from 199 (Mt) in 1961. A recent review shows that the Green Revolution continues to spread in favorable growing environments.

Rice improvement in Africa WARDA conducts rice improvement research in West and Central Africa, focusing on three distinct rice ecologies: upland, rainfed lowland, and irrigated land. Rice is a unique, and highly political commodity in Africa. The volume of rice consumed in West Africa exceeds $2.75 billion annually, of which $1 billion is spent on imports. Major rice producers in the region are Nigeria, Guinea, Côte d'Ivoire, Sierra Leone, Mali, Ghana, and Senegal which together account for 90% of rice cultivation and production .

Despite limited investments in agricultural research in the region, more than 197 improved varieties have been released since the 1980s, and 122 more are targeted for release in the next five years. 54 of the 197 varieties (27%) are related to CGIAR germplasm

enhancement, while an additional 31 varieties (16%) have parents or ancestors developed by CGIAR.

Using inter-specific hybridization techniques, WARDA has successfully combined the ruggedness of local African (*O. glaberrima*) rice species with the phenomenally high productivity traits of Asian rice (*O. sativa*) that was the mainstay of the Green Revolution. The new rice varieties, NERICAs or New Rices for Africa, resist droughts and pests and are able to thrive in poor soils. In Guinea alone, NERICAs are planted on 90 000 ha saving an estimated $10 million in rice import bills. Efforts are underway to accelerate diffusion of NERICAs throughout Sub-Saharan Africa through The Africa Rice Initiative. WARDA's research earned the CGIAR King Baudouin Award in 2000.

Rice improvement in Latin America CIAT has a mandate to promote sustainable increases in rice production and productivity in Latin America and the Caribbean region. Of the 299 rice varieties released from 23 national agricultural systems in the region, 95 varieties were released in Brazil. Of all the released varieties, 40% were crossed at CIAT. However, only 13 varieties in the region were developed from CIAT parents or ancestors. IRRI's International Network for Germplasm Evaluation and Research (INGER) has been instrumental in fostering rice collaboration in a region where only 19% of rice varieties released came from national agricultural systems.

Maize

Maize (*Zea mays* L.), a member of grass family Poaceae, is one of the most important dietary cereal grains, and the second-most abundant cultivated crop in the world. Maize (an open-pollinated crop unlike wheat and rice) is grown in a wide range of geographical areas, and its growing season ranges from 3 to 13 months.

The United States is the leading producer of maize. Developing countries account for the bulk of maize production (64% of area under maize cultivation and 43% of world harvests). In Sub-Saharan Africa, maize is the principal cereal crop. Of the 23 countries in the world with the highest per capita consumption of maize as food, 16 are in Sub-Saharan Africa. Maize provides 50% of the calories in diets in southern Africa, 30% in eastern Africa, and about 15% in West Africa. Despite its importance, maize yields average 1.4 $t\,ha^{-1}$, more than 1 $t\,ha^{-1}$ below the average for all developing countries.

Global impacts CIMMYT has a global mandate for maize improvement, and it targets lowland tropical, subtropical, mid-altitude, and tropical highland environments throughout the developing world. Mexico, where CIMMYT headquarters are located, is a center of origin for maize.

A recent study found that of all government-funded maize varieties released from 1966 to 1998, ~52% contained CIMMYT germplasm. The use of CIMMYT germplasm has increased over time, with 64% of all public-sector varietal releases containing CIMMYT germplasm.

Estimates of economic benefits from CIMMYT's maize research vary but based on the above results (21.2 Mha planted to CIMMYT-related varieties) and a conservative estimate of farm-level maize prices (US$120 per ton, on import parity basis) gross benefits range from US$1.3 billion to US$4 billion per year. These benefits take into account both germplasm improvements and better crop management practices.

A promising area of research is to develop a better understanding of apomixis, a plant's ability to reproduce asexually. Apomictic modes of reproduction are found most commonly in dicots Rosaceae and Asteraceae, and in the monocot Poaceae to which maize belongs. Apomictic gene technology is relevant to the problems of developing country agriculture because it will allow farmers to plant high-yielding maize year after year without having to buy costly hybrid seeds. Moreover, even with successive plantings, there is no risk of losing desirable traits in the progenies (e.g., high yields and resistance to stresses). A breakthrough in this area has the potential to boost agricultural production significantly, vastly improving food availability and farmer incomes.

CIMMYT maize breeder Surinder K. Vasal and biochemist Evangelina Villegas shared the 2000 Millennium World Food Prize for developing quality protein maize (QPM), a product of 30 years of research. QPM looks and tastes like normal maize but has nearly twice the amount of lysine and tryptophan, two amino acids essential for protein synthesis in humans. QPM is now being planted on 1 Mha in 20 countries, boosting food, nutrition, and income security.

Regional impact IITA, based in Ibadan, Nigeria, has a regional maize improvement mandate mainly targeting humid tropical and moist savannah zones of western and central Africa (WCA).

Maize accounts for more than 20% of domestic food production in Africa. Maize production has been growing steadily at an annual growth rate of 4% in West and over 2.35% in Central Africa. A survey of 12 countries (9 in West Africa and 3 in Central Africa), representing over 95% of maize

area showed that public breeding programs released 186 maize varieties, while the private sector released 81 maize varieties. There are three sources of germplasm for the released varieties: IITA, CIMMYT, and landraces. In the 1970s, IITA and CIMMYT supplied nearly 95% of the germplasm, a number that has continued to remain as high as 60% in the 1990s.

In 2000, two new maize varieties (Grace and Zm521) specifically adapted for southern Africa were released.

Sorghum

Grain sorghum (*Sorghum bicolor* [Linn.] Moench) is a native African cereal also widely grown in India, China, and the Americas. Sorghum is grown in 85 countries, and the crop ranks fifth in world cereal grain production and fourth in value (after rice, wheat, and maize). Sorghum is a hardy plant, tolerant to drought and well adapted to cultivation in saline soils; given its adaptability, sorghum holds promise for feeding growing populations in Africa and Asia, as feed grain in the Americas and Australia, for brewing purposes, and as fodder for livestock.

ICRISAT's research on sorghum improvement began in the 1970s, with India as the hub, and regional centers in west, eastern, and southern Africa, and in Latin America. A total of 405 improved sorghum cultivars are available in 43 countries in Africa, Asia, and the Americas. Of these, 146 were released from materials classified as ICRISAT-bred (64), ICRISAT parent (29), or ICRISAT network (53). In addition, average yields increased ($0.74\,\mathrm{t\,ha^{-1}}$ during 1981–94, up from $0.58\,\mathrm{t\,ha^{-1}}$ in 1966–81).

Pearl Millet

Pearl millet (*Pennisetum glaucum*) is a native African cereal cultivated in the arid and semiarid tropics of Africa and Asia. The species is morphologically complex, and 13 cultivated, 15 weed and 6 wild species have been recorded. Pearl millet accounts for only 3.5% of land under cereal cultivation globally and about 1% of total cereal production. Nevertheless, pearl millet and finger millet (*Eleusine coracana*) are important crops for smallholder farmers because they provide grain and fodder in harsh growing conditions (e.g., shallow, sandy, infertile soils having low water-retention capacity that are common in hot, dry environments).

ICRISAT has a global mandate for improving pearl millet and finger millet. During the 1980s, of the 49 varieties released worldwide, 23 varieties were of ICRISAT origin. During the 1990s, 52 of the 59 releases originated from ICRISAT materials. More importantly, many of the varieties released in 13 African countries were developed by ICRISAT. In India, where the national millet program was stronger, ICRISAT contributed parental material (rather than finished varieties).

ICRISAT's contribution in terms of adoption of improved cultivars has been sizeable. In Namibia, about 50% of total area pearl millet cultivation is under Okashana 1, a variety developed by ICRISAT. In Mali, adoption of improved cultivars increased from 12% in 1990 to 23% in 1995.

ICRISAT's work on pearl millet earned the CGIAR King Baudouin Award in 1996.

Barley

Barley belongs to the grass tribe Triticeae, to which wheats and ryes also belong. Barley is used mainly for animal feed, as malt for brewing beer, and is only marginally important as a human food. Barley is a hardy crop that can survive in harsh growing conditions (e.g., in nitrogen-depleted soils) and is therefore important for subsistence farmers.

Since 1980, ICARDA and CIMMYT have operated a joint Barley Breeding Program to develop HYVs with resistance to a broad range of diseases (stripe and leaf rusts, scald, fusariam head blight, and barley yellow dwarf).

During 1980–99, a total of 111 barley varieties were released in 23 developing countries. Using pedigree analysis, 78% of all barley varieties released were ICARDA-related material, 52% were ICARDA crosses (38% selected by ICARDA scientists and 14% by scientists partnering with national agricultural research systems). This collaborative breeding program has had significant impacts in Asia, West Asia and North Africa, and Latin America.

Conserving Biodiversity

Biological diversity – or biodiversity – refers collectively to the variety of life on earth. Nature's cornucopia of plants are an abundant source of food and fiber for the human family. According to a recent estimate, about 272 000 species of flowering plants have been described worldwide, with the true number being closer to 300 000. Each year about 2000 new species are added to *Index Kewensis*, botany's standard reference work.

For more than 30 years, CGIAR scientists have been collecting, characterizing, and conserving biodiversity. Currently, the CGIAR holds 532 508 samples of crop, forage, and agroforestry genetic resources in 11 gene banks around the world (Table 2). In 1994, CGIAR signed an agreement with FAO, placing the collections in public trust, available to researchers

Table 2 The CGIAR collections

Center	*Crop(s)*	*Number of accessions*
International Center for Tropical Agriculture (CIAT), Cali, Colombia	Bean	31 718
	Cassava	5 728
	Forages	18 138
International Maize and Wheat Improvement Center (CIMMYT), Mexico	Maize	20 411

Total		532 508

worldwide. In fulfilling its stewardship obligations, CGIAR invests $6 million every year to maintain these valuable resources for the benefit of humanity.

Since the 1980s, CGIAR gene banks have distributed over one million germplasm samples worldwide, and the vast majority of requests, 80% and more, came from developing countries.

Recognizing the challenge of creating a sustainable funding base for conservation activities, the Global Crop Diversity Trust (GCDT) was established to support global conservation of biodiversity.

Back to the Future

International cooperation in grain science has a brief but successful history, dating back to less than 50 years. The Green Revolution, called a "paradigm of knowledge for development," was a success. Its achievements have been foreshadowed by newer challenges, especially in Sub-Saharan Africa.

Agricultural research, conducted within a public goods framework, has achieved a track record of success. Rates of return to investment in crop research range from 16% to more than 100% per annum. Throughout history, agricultural research has been publicly driven and funded, with the benefits shared as well. But new realities mean that the successes of the past cannot easily be repeated in the future.

International interest in agricultural issues has waned. Record yields and low commodity prices have led to complacency. World Bank lending for agriculture has declined dramatically, from an average 31% of its total lending in 1979–81 to less than 10% in 1999–2000. A new rural development strategy "Reaching the Rural Poor" is helping to increase support for the agricultural and rural sectors in developing countries.

Deepening intellectual property rights (IPRs) have created a revolution in agricultural science and a race for exclusive property rights for agricultural

and biological knowledge. The US Patent Office received 4000 genetic patent requests in 1991, which rose sharply to 22 000 in 1995. One year later, patent requests increased to an unmanageable 500 000 year. Patenting activity is one indicator of innovation. The top 20 patenting countries in the world, with less than 15% of the world's population and 77% of gross national product account for 99% of all current patenting in the US. The challenges posed by these inexorable trends are twofold: to channel research to benefit poor people in developing countries and to achieve this during a period of declining public financial support for public agricultural research.

In 2002, the global area cultivated with transgenic crops was nearly 59 Mha, and the bulk of area was sown to soybean (62%), corn (21%), cotton (12%), and canola (5%). These crops are only marginally relevant to the agricultural development needs of developing countries.

The Commission on Intellectual Property Rights has warned that "too often, the interests of the 'producer' dominate in the evolution of intellectual property policy, and those of the ultimate consumer are either not heard or heeded." Public goods research where both knowledge and technologies are kept in the public domain offers a meaningful way forward to redress these imbalances.

The prospects for a new era in mobilizing grain science for development have never been better. The ongoing biological and information revolutions are transforming the science and science-for-development landscapes, creating unprecedented new opportunities for scientific cooperation. More than four decades of scientific cooperation has strengthened national research capacities in developing countries. The Internet is already the single-largest repository of biological information. Rapid advances in molecular biology are helping decode genomes of model plant species (*Arabidopsis thaliana*) and vital food crops such as rice.

Plant comparative genetics is predicted to unlock the secrets of crop plants. Knowledge of few major crops is being pooled, and extrapolation of information from well-studied species to orphan crops (which include many tropical species) is providing a solid-base for their improvement."

Grasping these opportunities will require new science-based partnerships – international, regional, national, and local – that are anchored in the common good. Consumers, farmers, policymakers, producers, and scientists all have a role to play. Public policies and institutions will need to address their concerns and protect their interests, while building an architecture of innovation that can continue to effectively marshal grain science for promoting sustainable agriculture.

Global Trends and The Commercial Sector

J H Skerritt, Australian Centre for International Agricultural Research, Canberra, ACT, Australia

Introduction

This article intends to synthesize some of the recent trends in the subject matter and institutional organizations of grains research internationally. Among these trends include a greater emphasis on demand-driven rather than science-driven research. Accompanying this is greater involvement of industry and farmer groups in setting research priorities, and in some cases, farmer groups are setting up and managing their own research trials. While *ex ante* economic impact assessment studies have shown that very significant returns on research investments have come from germ plasm development, there is an increasing emphasis in grains research on topics such as production sustainability, crop-livestock systems, systems modeling, and use of techniques from molecular and information sciences. Priority-setting processes and funding agencies have also encouraged greater collaboration between disciplines and between research institutes. It is now the norm for grains researchers to be part of large networks. The private sector has greater involvement in agricultural R&D than ever before particularly in developed countries. In the case of grains research, this sector is especially involved in linkages between seed business and biotechnology/life science concerns. Pardey and Beintema have calculated that since the mid-1990s, in developed countries, expenditures from the private sector in agricultural research have exceeded public expenditure.

Grains Research in the Commercial Sector

Grain Processing Companies

Most of the research carried out by these companies is concerned with practical applications, aimed to support their flour milling and bakery products businesses (including breakfast cereals), but some carry out more basic research and their staff contribute to industry research conferences and the scientific literature. Major examples in the US include the ConAgra Grain Processing Company in Omaha, NE, General Mills, Kellogg Company in Battle Creek, MI, and

Nabisco, New Jersey. Nabisco Research carries out rather fundamental studies on dough rheology and physical properties. Riceland Foods (Stuttgart, AR, USA) and Riviana Foods (Houston, TX, USA) are two very large manufacturers of rice- and soy-based food ingredients, and hence undertake applied research to support their markets. The National Starch and Chemical Company, Bridgewater, NJ focuses on cereal starch-based polymers and supports a significant research program including work on new adhesives, specialty food starches, and biodegradable packaging materials. Cargill has wheat flour milling and maize wet-milling divisions and provides grains-based feeds for livestock. Through Cargill Health and Food Technology, it focuses on nutraceuticals research, especially on developing products derived from soy. Other companies with an interest in research in soy products as nutraceuticals include DuPont Protein Technologies, St. Louis, MO; Central Soya Company, Fort Wayne, IN; and Schouten USA, Minneapolis, MN.

In Japan, two large milling companies, Nisshin Flour Milling and Nippon Flour, have played an important role over the last few decades in increasing the consumption of wheat in the Japanese diet. They also carry out a significant amount of research. In the UK, Rank Hovis and ADM Milling, Associated British Foods, Allied Bakeries and British bakeries are among the largest milling and baking companies, and they conduct some in-house research and technology development. Barilla, has a large cereal products research center in Italy, while in Australia, Goodman Fielder, Weston Foods, and Penford starches have active technology development programs. Other companies within the oilseed crushing and animal feeds industry also have applied research programs.

Baking Industry Associations

Industry associations are also an important provider of research and technical services in the grains industry. In the UK, the Campden and Chorleywood Food Research Association, Chipping Campden, is a membership-based organization that provides research and consultancy services for cereal-processing companies. The RHM Technology Centre in High Wycombe, Bucks, UK, is part of the RHM (Rank Hovis McDougall) group. The center conducts theoretical and experimental studies in cereal (especially wheat) food science and technology. It also undertakes R&D projects for other commercial and government clients. Leatherhead Food International started as a UK food-industry association, but has evolved into an independent provider of food research and market information. In France, ARVALIS Institut du végétal, a farmers' organization, carries out research on grains to satisfy the demands of markets and consumers. The American Institute of Baking, in Manhattan, KS, USA was founded by the North American baking industry to apply research findings to the industry in the US and internationally. Emphasis of the research includes cereal science, baking technology, nutrition, and food safety.

BRI Australia Ltd. (formerly the Bread Research Institute) is an independent Australian organization supported by the industry through membership fees and by competitive government and industry research grants. It carries out applied research in flour milling, baking, and Asian foods. The Japan Institute of Baking Technology in Tokyo, also plays a similar role.

Seed and Grain Biotechnology Companies

In a large number of cases, these two sectors have merged since the 1990s. A brief description of some of the largest multinational companies is in Table 1. Many of the companies were initially agrochemical suppliers, but the development of transgenic, herbicide-resistant grain crops provided them with an opportunity to market the seed and agrochemical as a package. Several companies have an obvious leadership role in the development of agrochemicals and transgenic crops. However, the merger of many of these enterprises with seed companies increased their importance in breeding and agronomy and, more significantly, resulted in the consumer benefiting from research on transgenic crops. Genetic engineering has been carried out mostly on maize, cotton, soybean, and canola. To achieve resistance to herbicides and insecticidal activity, genes for *Bacillus thuringiensis* toxin were incorporated. For example, Monsanto Company's products (St. Louis, MO) include herbicide-resistant soybeans, canola, and corn and insect-protected corn. A wider range of traits and crops such as wheat, as well as output traits relating to processing quality is now being targeted. For example, Syngenta is currently developing a transgenic *Fusarium* head blight-resistant wheat. The companies also have broader genomics and gene-discovery programs. Syngenta and Basel Switzerland through its Torrey Mesa Research Institute in California, have published a rice genome analysis and made the information publicly available.

Research and development budgets of numerous companies run into several hundreds of millions of US dollars, comparable with government agricultural R&D budgets in some medium-sized developed countries.

Brewing Companies

These form the second largest group of private sector companies carrying out grains research. The largest brewing industry research organization is BRI (Brewing Research International), in Nutfield, UK. They undertake research on behalf of their members worldwide on aspects of food safety, barley and malt quality, fermentation, and beer quality. In addition, a number of the major brewery companies have significant in-house R&D activities, such as the giant US brewer, Anheuser-Busch, the European Brewer, Interbrew, and Tepral (Strasbourg, France) as well as smaller brewing companies worldwide. Applied research on barley and malt composition and quality is carried out.

The research activities of Carlsberg Brewers spread much further than malting and brewing. Since the establishment of research laboratories in 1876, Carlsberg has made major contributions to fundamental chemistry and such as the development of the Kjeldahl protein analytical method. There are now three affiliated research centers located near the Carlsberg brewery site in Copenhagen, Denmark. The first, Carlsberg Research Center, emphasizes both basic and applied research on grain protein and carbohydrates and their reactions during brewing, and biochemical studies on amino acid transport, protein-folding seed germination, and yeast physiology. The second, Carlsberg Research Laboratory, emphasizes barley breeding, genetics, microbiology, and plant biotechnology. Recently, a third laboratory, Carlsberg Biosektor, has been established, covering a range of biotechnologies designed for commercialization.

Major Trends among Grains Research Organizations

Increased Planning and Collaboration

Since the 1980s, there have been significant changes in the organization and management of grains

research. There has been a greater degree of planning and an increased degree of focus in the programs of many research organizations. Much of the increased focus has been on market needs – it is hard to criticize the important influence this has had on breeding programs, grains chemistry, and processing research. Greater linkages between research on grain production and marketing is important so that the research facilitates farmers who engage in market-specified production, as opposed to research to underpin increased production of grain as a bulk commodity. A less *ad hoc* approach in the activities carried by government research organizations has to an extent been forced on them by funding agencies – research centers have often moved from being provided with guaranteed government allocations to being dependent on competitive funding. Research planning exercises have been in favor in a number of commercial and government organizations across the globe. It is unclear to what extent individual creativity has been affected by these trends – certainly there may be less scope for curiosity-driven grains research.

An overarching trend has been the greater level of cooperation between research organizations; funding networks such as those established by the EC and Australian Government CRC system have facilitated this trend, as well as organizational changes in major government departments such as US Department of Agriculture. However, it is probably still true to state that US grain research appears less well coordinated at a national level – although locally, the close interactions between a number of USDA-ARS facilities and land grant universities is very productive. The increased importance of networks in many areas of science is a response to the increased cost of carrying out research plus an increasing realization that problems are multidimensional and are best addressed through multidisciplinary approaches. Certainly there has also been pressure from governments and funding bodies for research providers to network more, in part to avoid duplication of research and also to ensure that particular subprojects are carried out by the most qualified group.

In the developing world, development banks such as the World Bank and Asian Development Bank have funded reform programs that encourage rationalization in the number of research providers as well as greater coordination. Scientist-to-scientist collaboration across institutional and national boundaries has been greatly facilitated by the communications revolution – the ability to email large amounts of data and draft manuscripts for immediate receipt has totally changed the possibilities for collaboration compared with only a decade ago. Globalization in industry – both through development of alliances between commercial research providers in different countries, and increased emphasis on grains breeding for export markets have also become more important forces. Markets are becoming more differentiated so there is an increased emphasis on grain quality – both as a target for breeding efforts, additional to yield, and disease resistance – and on research aimed at improving the understanding of the genetic, chemical, and structural factors underpinning grain quality.

Changes in Research Subject Matter

Grains agronomy programs have had to develop a stronger research emphasis on sustainability of production in recent years, responding to a shift in community values as well as serious scientific concerns about the long-term impact of some grain farming practices. Concerns about effects of irrigation, salinity, acidification (especially with certain legume crops), loss of soil, and of soil structure have led to an increase in research on reduced tillage, water conservation, and weed control, and maintenance of soil fertility. Indeed, the major factor underpinning sustainable agriculture has been the ability to feed the world's increasing population through enhanced yields, and with the exception of a few communities, grains, especially cereals are the central element of almost diets. Since the 1940s, there has not been a significant increase in the area of land available for agriculture. However, it is true that with the expansion of irrigation systems and with new varieties and increased fertilizer use in the middle of the twentieth century, there was an expansion of grain-growing areas. Since the 1980s, the expansion of irrigated areas has largely ceased and so production increases must come from increases in yield. Therefore the key contributor to sustainability in grains production will continue to be productivity; increases are important for both developing and developed country farmers, as the terms of trade for farmers continue to become poorer. An even greater challenge to developing countries is how North American and European governments shield their grain farmers from market realities through subsidies.

Livestock are becoming a very significant consumer of grains worldwide; the trend is especially noticeable in developing countries, where meat consumption has increased significantly through the 1980s and 1990s, from a low base. Many of these animals are now grain-fed, so research has had to underpin

the increased importance of grains for feed rather than food applications. This research is also driven by increased intensification of monogastric animal production, including in developing countries. In many countries, farmers are not solely grain growers or cattle or sheep farmers, but manage a mixed enterprise. There has been a more active development of systems-based research to address their needs.

Institutional Trends

Another major change in the nature of agricultural research since the 1980s, particularly in the US and Europe, has been the shift in balance of research to a greatly increased role of the private sector. In some parts of the world, such as Europe, there has been a long history of significant plant breeding efforts being carried out by industry, in others, such as Australia (with the exception of hybrid cereals), almost all plant breeding was formerly carried out by government and universities. Different countries also have different patterns of involvement of universities in breeding, although in the process of training breeders some universities have developed significant breeding programs or in other cases have been the mainstay of breeding efforts for a region or country. Several factors, some of which are interdependent, have given rise to greater commercial involvement in grains breeding, including increased importance of plant breeders' rights, development, and application of biotechnology in grain science, shrinkage of government support for agricultural research, and the increased importance of intellectual property protection. In some cases, privatization of former public sector plant breeding institutes has taken place, such as PBI in the UK (once Plant Breeding Institute, now Plant Breeding International).

The other industry that has become more involved in grains research are farmers themselves. Farmer-driven groups now often have a key role in identifying research priorities as well as being a vehicle for dissemination of research results – farmers groups directly manage on-farm adaptive research trials on technologies such as rotations, weed control, and reduced tillage. Realizing that both small and large farms are often diversified enterprises, grains research has a much greater emphasis on farming systems than in previous year. The influence of farmers is important in fitting grains research into a wider farming systems context. Organizations that use farmers' levies to fund research such as the Home-Grown Cereals Authority in the UK or the Australian Grains Research and Development Corporation have also been instrumental in encouraging greater farmer involvement.

Most grains science is done within institutional structures, which have evolved from a range of historical situations, rather than having been developed with a consideration of whether the institutional structures fit the needs of the twenty-first century. In many state or provincial-based departments, there is a linkage of cereal breeding and cereal chemistry, and the scientists involved carry out a service function as well as independent research – often creating a tension between the time spent on the two, but with the advantage that the research objectives are informed by genuine industry problems. There are few grain science institutions in the world that cover all of cereals, legumes, and oilseeds. Instead, there may be research clusters within university agronomy or agriculture faculties or grains researchers within plant science or crops research organizations. It is more usual for postharvest-technology institutions or grain-storage laboratories to consider various issues relating to cereals and other grains on the basis that storage and handling of grains as durable commodities has common research challenges. Some institutes cover several cereals, although usually with a focus on those relevant for their country or targeted group. For example, wheat and barley are sometimes studied together. Some of the equipment and techniques are common, while others specialized – for example, while Falling number is used as a measure of postharvest sprouting for both wheat and barley, dough rheology testing is specific to wheat. Specialized grain science departments are found in a small number of US universities. Arguments for this model are the critical mass of researchers and ability of students to train in aspects from grains breeding to postharvest technology. On the other hand, such departments can lack linkages to discovery science and to a broader range of disciplines in agriculture and science.

One of the lessons of modern molecular biology is that techniques such as those in functional genomics are often readily transferable between grains, other crops, microorganisms, and animals. The high degree of synteny tells us that gene structure and function is conserved across cereals, and the great similarity of their physiological and biochemical processes often makes it simple to utilize research ideas and techniques between different grain crops. There are no definitive answers to the issue of an optimal institutional structure for grains research other than to assume that earlier structures need not necessarily be

more important than ever for breeders, agronomists, crop protection scientists, and researchers of processing quality to interact.

RICE

Contents

Overview

B O Juliano, Philippine Rice Research Institute, Los Baños, Laguna, Philippines

Global Distribution, Varieties, and Commercial Importance

Rice is the most important crop in the world in terms of total developing world production (480×10^6 tons (t) of rough rice) and the number of consumers (2.5 billion) dependent on it as their staple food. Rice is widely grown in over 100 countries, in every continent (except Antarctica), from 53°N to 40°S, and from sea level to an altitude of 3 km. Total production in 1999 was 596×10^6 t of rough rice. Asia accounts for 134×10^6 ha out of the 149×10^6 ha world area that is under for rice cultivation. Mean rough rice yield was 3.84 t ha^{-1} in 1999. About 90% of the world's rice is grown and consumed in Asia. Major rice producers in 1999 were China, India, Indonesia, Bangladesh, Vietnam, and Thailand. In terms of water regime, 54% of the total area under rice cultivation was irrigated in 1991, 25% rainfed lowland, 13% upland, and 9% as flood-prone wetland, corresponding to total rough rice production of 76% from irrigated, 16% from rainfed lowland, 4% from upland, and 4% from flood-prone wetland. Since the rice-growing area is shrinking, rice production must keep up with the 1.7% per year increase in population in tropical Asia through increased yield.

There are estimated to be ~100 000 rice varieties; only a small proportion is actually widely cultivated. They vary in grain weight, size and shape, degree of dormancy, longevity, and seedling vigor, and some have red to purple-black pigments. About 75% of area under rice cultivation in Asia is planted with varieties of improved semidwarf plant type with erect leaves. The newer, improved varieties have

similar yield potential as the first variety (IR8) but have better resistance or tolerance to biotic and abiotic stresses. "Super" rice being bred has fewer tillers but all of them are productive.

Structure of the Grain

The rice grain (rough rice or paddy) consists of an outer protective covering, the hull (husk), and the edible rice caryopsis or fruit (brown, cargo, de-hulled or de-husked rice) (Figure 1). Brown rice consists of the outer layers of pericarp, seedcoat and nucellus, the germ or embryo, which are maternal tissues, and the endosperm. The endosperm consists of the aleurone layer and the starchy or inner endosperm. Pigmentation is confined to the pericarp, but there is varietal difference in the extent of retention of pigment with the degree of milling. The aleurone layer encloses the embryo.

The inedible hull constitutes 16–28% (mean 20%) of rough rice weight. Brown rice consists of 1–2% pericarp, 4–6% aleurone plus nucellus and seedcoat, 1% embryo, 2% scutellum, and 90–91% endosperm. The aleurone and embryo cells are rich in lipid bodies (spherosomes, 0.2–1.5 μm) and in protein bodies (aleurone grains) containing inclusions of phytic acid bodies or globoids (1–3 μm).

The endosperm cells are thin-walled and packed with amyloplasts containing polyhedral compound starch granules ~3–9 μm in size. Protein occurs mainly in the form of large (1–2 μm) and small (0.5–0.8 μm) spherical protein bodies and crystalline protein bodies (2–4 μm). Spherical protein bodies (PB I) are rich in prolamin (alcohol-soluble protein) and crystalline protein bodies (PB II) are rich in glutelin (alkali-soluble protein). Spherosomes are present in the subaleurone or the two outermost cell layers of the endosperm.

Handling, Grading, and Storage

Tropical rice is usually harvested at 20% or more moisture content, ~30 days after 50% flowering, when grains will provide optimum total and head rice yields. Moisture content at harvest is lower during the dry season than in the wet season because of more sun-drying of grain even before harvest. The actual period of dry-matter production is no more than 14–18 days, after which the grain undergoes drying. The ripening period is longer in japonica rice.

Rice is still, in most cases, harvested by cutting the panicle with enough stem to allow threshing by hand. The panicles are sun-dried on the bund prior to threshing by hand, treading by people or animals, or processing by mechanical threshers. When threshing is delayed while the cut crop is stored in heaps, "stack burning" often results as a consequence of the anaerobic respiration of microorganisms on the straw (70–80% moisture) and grain. Yellow or tan grains are formed when the panicle temperature reaches ~60°C for a few days. The discolored grains have a better head rice yield and are more translucent than control grains. The mechanism seems to be nonenzymic browning, which results in decreases in the lysine content of the protein (~0.5%) and in the true digestibility to 92% and NPU to 61%.

Delayed harvest in rainy weather frequently leads to grain sprouting on the panicle, particularly for nondormant japonica rice. Lodging may also cause sprouting for nondormant rice. The incidence of the heavy rains (cyclones) during the harvesting season in India correlates with aflatoxin contamination of the crop.

Solar radiation is normally used, particularly in the dry season, to dry rough rice. Drying capacity is limited in the wet season, when more rice is grown because of water availability. Flash dryers are ideal for the first round of drying of harvested rough rice, to decrease the moisture content to 18–20% and the grain may be safely stored for 4–5 weeks before final drying. Grain cracking is minimal above 18% moisture. But no mechanical dryer has been adopted widely by Asian farmers.

An important property of harvested grain is its moisture content: 14% on a wet-weight basis is considered a safe storage value; grains become susceptible to fissuring from moisture adsorption stress below critical moisture contents of 12–16%, depending on variety. The glass transition temperature (T_g) concept has been used to explain grain fissuring during drying: below the T_g, e.g., at 40°C, there is no risk of fissuring, but above the T_g, in the rubbery state, e.g., at 60°C, tempering is required to prevent fissuring.

Rice is stored as rough rice in most of the tropics in sacks to maintain variety identity, whereas in Japan it is stored as brown rice. Storage space is reduced, but brown rice is more sensitive to environmental stress in the absence of the insulating enclosing hull and readily fissures in transit. Rubber rollers minimize bruising of the brown rice surface and improve the shelf life of the de-hulled grain. Bulk or bin storage is practiced in some countries. They are transported in 50 kg sacks or in bulk.

Storage changes or aging of sun- or oven-dried rough rice for up to 2 months after harvest, at ambient temperature >15°C, improve milling yields. This ensures that the milled rice expands more during cooking and is hence flakier. Heating during grain drying accelerates aging. Aged rice is cream colored. Aging improves the texture of tropical rice, but not in japonica rice, wherein stickiness is prized.

Processing

The per capita consumption of milled rice was 86 kg per year in 1999 in Asia in comparison to 4–31 kg in other continents. About 20% of rice is consumed as parboiled rice. Parboiling consists of boiling or steaming steeped rough rice until the hull starts to open and then cooling and drying the gelatinized grain. Diffusion of bran B-vitamins into the endosperm occurs during parboiling. Mycotoxins are a potential problem in parboiled rice. Milling involves de-hulling, followed by removal of the pericarp, seedcoat, nucellus, aleurone layer, and the germ, i.e., the outer 7–10% of the brown rice, either by friction or abrasion. In the Engelberg mills, hull and bran are removed together in one step with high-grain breakage. Milling is done in several steps in modern cone mills, with tempering carried out in between to minimize breakage. Many modern mills have shifted to milling at >14% moisture to minimize grain breakage and to moisture-mist treatment (through hollow shaft) during milling to soften the bran and improve surface gloss.

There is no international standard for milled rice size and shape. International Rice Research Institute (IRRI) uses the following scale for size: extra long, >7.50 mm; long, 6.61–7.50 mm; medium, 5.51–6.60 mm; and short, <5.50 mm; whereas Food and Agriculture Organization of the United Nations (FAO) uses: extra long, ≥7.00 mm; long, 6.00–6.99 mm; medium, 5.00–5.99 mm; and short, <5.00 mm. For grain shape based on length : width ratio, the following scale is used by IRRI: slender, >3.0; medium, 2.1–3.0; bold, 1.1–2.0; and round, ≤1.0; and by FAO: slender, >3.0; bold, 2.0–3.0; and round, <2.0.

Grades are based on grain size and shape, degree of milling, percentage head or whole-grain milled rice, immature grains, damaged (discolored) and heat-damaged grains (chalky grains, red grains, and red-streaked grains), aroma, and organic and inorganic extraneous matter.

Only ~4–5% of the world's rice production enters the international trade. The major exporters in 1997 were Thailand, Vietnam, India, USA, and Pakistan. Major importers in 1997 were Iran, Brazil, Nigeria, Philippines, Iraq, Saudi Arabia, Malaysia, South Africa, and Cote d'Ivoire.

Chemical and Nutritional Composition

Rice has one of the lowest protein contents (7%) among the cereals. The bran layers and embryo are richer in nonstarch constituents than the milled rice (Table 1). The major nutritional advantage of brown rice over milled rice is its higher content of B-vitamins. Although higher in minerals, bran phytic acid and probably dietary fiber in the aleurone form complexes with minerals and proteins, reducing their bioavailability. Recent zinc bioavailability data in rats showed that the amount of zinc absorbed from brown rice was even higher than that absorbed from milled rice. Confirmatory human studies on iron and zinc biovailability in Filipino rice-fish vegetable diet based on brown and milled rice are underway to resolve this question and to determine the required precautions. The energy content of brown rice and bran is higher than that of milled rice due to the higher fat content. Rice has no vitamin A, C, or D.

Although cereal proteins are deficient in lysine, rice protein has one of the highest lysine contents among them, corresponding to an amino acid score of 59% in milled rice (based on the amino acid pattern of 5.8 g lysine per 16 g N as 100%, proposed by Food and Agriculture Organization/World Health Organization/United Nations University (FAO/WHO/UNU) (Table 2)). The solubility fractions of protein are

Table 1 Comparison of nutrient composition of brown rice, milled rice, and rice bran

Property	*Amounts (per 100 g)*		
	Brown rice	*Milled rice*	*Rice bran*

Sources: Juliano BO (ed.) (1985) *Rice: Chemistry and Technology*, 2nd edn., 774p. St. Paul, MN: American Association of Cereal Chemists; US Department of Agriculture (1998) *Nutrient Database for Standard Reference, Release 12*. Riverdale, MD: USDA.

~15% albumin–globulin (water and salt soluble), 20% prolamin (PB I), and 65% glutelin (PB II) in milled rice. Bran proteins are 66–98% albumins. Prolamin is poorest in lysine but rich in sulfur amino acids. The high lysine content of rice protein is due to low prolamin content.

Energy digestibility is higher in milled rice than in brown rice due to lower dietary fiber and phytic acid levels as verified by poor energy digestibility of rice bran (Table 2). Protein true digestibility (TD) of milled rice is also higher than that of brown rice, but the biological value (BV) is lower, resulting in similar net protein utilization (NPU). Bran protein has lower TD but higher BV than brown and milled rice proteins. Amino acid score, corrected for TD in rats, proposed by FAO as a protein quality index, showed similar values to NPU for the rice proteins. Black or purple rice has lower NPU (72%) than brown rice and higher tannin level (0.6%) than red (NPU 83% and 0.2% tannin) and nonpigmented rices (NPU 97% and ≤0.02% tannin). However, their milled rices have identical NPUs. Rice complements legumes in amino acid composition for human diets.

Cooking and parboiling reduce TD in growing rats by 5–15%, with a corresponding increase in BV but little change in NPU. However, lysine digestibility remains close to 100%, whereas cysteine digestibility drops to ~82%. The fraction that remains in the feces as fecal protein particles represents the lipid-rich core of large PB I, with less than 1% lysine in its protein and a high cystine content. PB II is readily digested.

Starch varies in apparent amylose content (by iodine colorimetry): waxy, 1–2%; very low amylose, 2–12%; low, 12–20%; intermediate, 20–25%; and high, 25–33%, all on milled rice dry weight basis.

Glycemic index of cooked brown rice tends to be lower than that of cooked milled rice due to higher phytic acid and fiber in brown rice. Among cooked milled rice, glycemic index decreases with increasing amylose content regardless of cooking method (Table 3). Processing, including parboiling, tends to reduce glycemic index. Resistant starch is <5% and may not be as important as glycemic index in humans.

Breeding efforts to improve the nutritional value of rice grain include higher micronutrient density;

Table 2 Essential amino acid profile and energy and nitrogen balance in growing rats of raw brown rice, milled rice, and rice bran

Property	*Brown rice*	*Milled rice*	*Rice bran*

higher iron, zinc, and vitamin A contents; low phytic acid (high phosphate) and prolamin content; and absence of lipoxygenase-3 activity and of allergenic globulin, and transgenic rice endosperm with vitamin A, with soybean glycinin gene, and with soybean ferritin gene.

Food Uses

There are various ways of cooking milled rice. In tropical Asia, they are prewashed to remove dirt, but this results in losses of B-vitamins and fat. Presoaking for 30 min reduces cooking time (particularly of parboiled rice). During soaking, grain cracking is minimized by adjusting milled-rice moisture content to 15% by high-pressure hydration. Rice may be cooked in the water it absorbs, or boiled in excess water and the cooking liquor discarded. A steaming process is used in Indonesia for waxy rice. Oil or ghee may be added in the Middle East, to reduce surface stickiness. Enriched rice premixes containing iron and B-vitamins resistant to washing have been developed for rice, but have not been popular due to additional expense; the enriched rice can be readily distinguished from ordinary grain.

Apparent amylose content (AC) correlates positively with water absorption and volume expansion during cooking, and with the hardness of boiled rice. South Asian consumers prefer high-AC, intermediate-gelatinization temperature ($GT > 70°C$) rice; Southeast Asians prefer intermediate-AC, intermediate-GT rice. Japonica rice preferred in Japan, Korea, Taiwan, and northern China are mainly low AC, low GT ($\leq 70°C$), with some varieties having intermediate AC being preferred in Europe. Steamed waxy rice is consumed as a staple only in Laos, and north and northeastern Thailand. Amylopectin of low-GT, high-AC rice has longer mean chain length than amylopectin of intermediate-GT, high-AC rice. Among waxy and low-AC rice, low-GT rice has softer cooked rice than high-GT rice, but among intermediate- and high-AC rice, intermediate-GT rice has softer cooked rice than low-GT rice. Longer-chain amylopectin contributes to the flaky cooked rice of low-GT, high-AC rices. Amylopectin staling is less in low GT cooked rice than in higher-GT rice within each amylose type and is reversed by heating.

Specialty rice include Italian Arborio rice for making risotto, waxy rice (sweet rice, with opaque grain), Thai Jasmine rice (aromatic low AC long grain), and Punjab Basmati (aromatic intermediate AC long grain that elongate when presoaked rice is cooked). 2-Acetyl-1-pyrroline was the first major aroma principle identified in raw and cooked aromatic rice and bis-(2-methyl-3-furyl)-disulfide,

2-aminoacetophenone, and an unknown compound have been recently identified.

Various rice products are prepared for which specific AC types are preferred (Table 4). Freshly and well-milled rice is preferred for rice products to prolong shelf life by minimizing fat rancidity in the stored products. Parboiled rice are preferably high and intermediate AC, while extruded and flat noodles use mainly aged, high-AC low-GT rice. Rice with a low starch GT is preferred in rice puddings, breads and cakes, and beer adjuncts. Waxy and low-AC rice are preferred for rice wines (for higher ethanol yield) and in frozen sauces, desserts, snacks, and sweets because of their slow staling rate. Rice crackers are prepared from waxy and nonwaxy rice. Parboiled rice is preferred over raw rice for "idli" (pudding) and "dosai" (cake) with rice : black gram usually fermented at 3:1 weight ratio. Thermophysical properties of starch such as T_g and GT, enthalpy of raw starch, staled amylopectin melting (45–60°C), amylose-lipid complex I (<100°C) and II (>100°C) melting, and staled amylose melting (>130°C) of gelatinized starch affect the properties of rice products in addition to amylose–amylopectin ratio and protein content.

Use of rice bran in cereal products increased in recent years due to the hypocholesterolemic effect (in humans) of the factor(s) in the high (up to 7%) unsaponifiable fraction of its oil, such as γ-oryzanol (ferulate ester of cycloartenol, 24-methylene-cycloartanol, and campesterol) and tocotrienols, an analogue of tocopherol (vitamin E). Defatted bran has no hypocholesterolemic activity, unlike in oat where the active principle is soluble β-glucan. Inactivation of antinutrition factors – trypsin inhibitor, oryzacystatin and hemaglutinin-lectin, and lipase and lipoxygenase that are concentrated in the rice bran by heat treatment and extrusion cooking – improves

Table 4 Apparent AC type and other properties reported as preferred for various processed rice products[a]

Rice-based product	*AC type*				*Other properties*
	Waxy	*Low*	*Intermediate*	*High*	
Parboiled rice	+	+	++	++	
Precooked/quick cooking	+	+	+	+	Based on table rice AC
Expanded rice	+	+	+	+	AC not a major factor
Expanded rice, molded		+	++	+	Waxy, does not expand
Rice cereals/snacks		+	+	+	Low fat, texture, affected by AC
Extruded rice food		+	+	+	Low fat
Rice-based infant food			+	+	Low fat
Rice flour and starch	+	+	+	+	Wet milled, freshly milled rice
Rice crackers/biscuits	++	++	+	+	Japanese "arare," "senbei"
Rice puddings	+	+			Japanese "uiro"
Rice breads		+	+	+	Low GT
Unleavened rice bread				++	Pakistani "roti"
Rice cakes, steamed	+	+	+		Fermented/nonfermented
Rice cakes, baked	+	+	+	+	Low GT, for celiac disease patients
Flat noodles/rice paper		+	+	++	Low shear process
Extruded rice noodles			+	++	Hard gel consistency
Rice pasta		+	+	+	Raw and parboiled rices
Rice frozen sauces	+	+			Gel stability
Rice desserts/sweets	+	+			Gel stability
Fermented rice foods		+	+	++	Parboiled idli, dosa
Rice wines	+	++			Low protein, low fat
Beer adjunct		+			Low GT, low fat
Rice in batters and fried foods	+	+	++	+	Crunchy texture
Rice in thickeners	+	+			Gel stability

the shelf life of the bran and its nutritional value to poultry. By contrast, the antinutrition factor, phytic acid, is heat stable. Phytic acid in rice bran and brown rice has been recently reported to have antioxidant and medicinal activity in preventing some types of cancer. Phytic acid content of rice bran is highest among cereal brans (3–8% phytic acid, Table 1). Brown rice consumption is being popularized in and outside Asia. Recent studies on rats showed that zinc bioavailability is even higher in brown rice than in milled rice. Confirmatory human studies consuming local rice-based diets are needed to insure that brown rice will not aggravate the anemia problem in the rural population by further reducing iron bioavailability. Brown rice is a better source of vitamins and antioxidants than bran due to breakdown of antioxidants during processing and storage of rice bran. "Organic" rice is also in the market with lower pesticide residues, but higher price.

Total rice bran oil production in 1986–88 was 600 000 t year^{-1}, mainly in India, China, Japan, and Vietnam, according to FAO. It was estimated to be less than 800 000 t in 1997. This represented only 11% of potential bran oil production requiring immediate oil extraction or stabilization due to bran lipase. The high hull-contamination (70%) of rice bran produced by Engelberg mills makes oil extraction from their "bran" uneconomical. Essential fatty acid content of rice oil is 34.2% of 18:2, and 1.5% of 18:3. Levels of oryzanol and tocotrienols and unsaponifiable matter differ among crude oils and oryzanol and tocotrienols may be reduced up to 90% by conventional refining and deodorizing.

Introduction

Rice is arguably the world's most important staple food crop and a primary food source for more than half of the world's population. More than 90% of the world's rice is produced and consumed in Asia where about three-fifths of the Earth's people live. A 70% increase in rice supply by the year 2025 will be required to maintain the food-population balance. Breeding new rice varieties with high yield potential, highly resistant to biotic and abiotic stress, and with high eating and nutritional quality is one of the best ways to help satisfy this demand.

Rice genetics is the science of studying heredity in rice and related plant species, and is the basis for all sound, effective, and efficient breeding programs (*see* **Rice**: Breeding). It provides both basic principles and applied selection methods for rice breeding. Better understanding of the inheritance of rice traits will stimulate significant progress either in selection efficiency or in accuracy for rice breeding. Greater insight on the molecular genetic basis of the detailed functioning of metabolic pathways will better explain how the plants inherit traits from their parents and how phenotypes are developed and regulated.

Cultivated rice (*Oryza sativa* L.) is a diploid species with 24 chromosomes (12 pairs). Besides *O. sativa*, 23 additional species have been identified in the *Oryza* genus, most of which are diploid, but a few are tetraploid (*see* **Rice**: Wildrice, Zizania). Rice has the smallest genome (~430 Mb) among the major cereals (Table 1). Rice is a monocot and a grass, and it has been regarded as a counterpart of the dicot model system, i.e., *Arabidopsis thaliana*, in genomic studies.

Table 1 Genome size and number of genes of cereal crops

Species	*Genome size (Mb)*	*No. of genes*	*Predicted kb/gene*
Rice	430	30–50 000	15
Sorghum	750	30–50 000	15–25
Maize	2500	50 000	50
Barley	4800	30 000	160
Diploid wheat	5300	30 000	175

Therefore, rice has become the best-characterized cereal at the molecular level of any crop species. The entire genome of the two subspecies of cultivated rice, *indica* and *japonica*, was sequenced in 2002. Rice is hence the first crop and the second plant to have had its genome sequenced.

The development of DNA molecular markers has helped to explore the information stored in the rice genome, and to understand the genetic behavior for many of the traits of agronomic importance at the molecular level by using genetic linkage maps. This article summarizes recent advances in rice genetics especially at the molecular level.

From Quantitative Genetics to Molecular Quantitative Genetics

The Basis of the Classical Quantitative Genetics

Rice traits under genetic study can be assigned to two broad categories according to their complexity in inheritance: qualitative traits and quantitative traits. Qualitative traits can be classified into discrete classes and are determined by either one or a few genes which show Mendelian inheritance. To study their inheritance requires differences in the expression of alleles at individual loci (genes), usually designated as the dominant allele (wild-type allele) and the recessive allele (mutant allele). The inheritance of qualitative traits is predictable, and the genotype (G) of individuals is determined by their phenotype (P). Quantitative traits cannot be classified into discrete classes, and the variants show normal distribution in a segregating population. Quantitative traits are genetically controlled by polygenes or minor genes (each of which may also show Mendelian inheritance), but are greatly modified by environment. To study their inheritance requires large-scale experiments and statistical analysis to estimate genetic parameters.

The phenotypes (P) of individuals and families in replicated traits include genetic effects (G) and environmental effects (E), which can be expressed in a linear model as $P = G + E$. If the genetic effects are not consistent across environments, there are interactions between genotypes and environments. In such a case, the linear model becomes $P = G + E + GE$. The genetic effects (G) can be further partitioned into additive genetic effects (A), dominance effects (D), and epistatic effects (I), and expressed as $G = A + D + I$. The additive effects indicate the total effects for all the loci that include the genes affecting the trait; the dominance effects are the interactions of alleles at a locus; and the epistatic effects are the interactions between alleles of different loci. Additive genetic effects can be selected directly, whereas the interaction effects (D and I) are not transmitted directly from parents to their offspring. Estimation of A, D, and I requires different types of progenies in a well-designed experiment. The total variation among phenotypes (σ_P^2) is attributable to the genetic and environmental effects and the interaction of genetic and environmental effects. The broad-sense heritability of a trait can be expressed as $h_b^2 = \sigma_G^2/\sigma_P^2$. If the total genetic variation can be partitioned into A, D, and/or I, the narrow-sense heritability can be calculated as $h_n^2 = \sigma_A^2/\sigma_P^2$.

Molecular Dissection of Quantitative Traits

Classical genetic analysis can only interpret the effect of all polygenes as a whole; it cannot effectively determine the number of genes expressed for the trait, the position of genes on chromosomes, and the effect of each gene. However, these problems can be resolved with the application of genetic markers together with the help of genetic linkage maps, by dissecting quantitative traits into quantitative trait loci (QTL).

Genetic markers include morphological markers, biochemical markers (e.g., isozymes), and DNA markers. The number of morphological and biochemical markers that can be identified is very limited. DNA markers denote variations in the pattern of DNA fragments or sequences in different individuals. The differences are referred to as DNA polymorphisms, which arise as a result of insertions, deletions, duplications, and substitutions of nucleotides. Restriction fragment length polymorphisms (RFLPs) is the first class of characterized DNA markers first reported in 1980. Since then, many other types of molecular markers have been developed, such as random amplified polymorphic DNA (RAPD), simple sequence repeat (SSR) or microsatellite, inter-SSR (ISSR), sequence tagged site (STS), amplified fragment length polymorphism (AFLP), and single nucleotide polymorphism (SNP).

The abundance of DNA markers allows genetic linkage map development. Construction of a genetic linkage map involves: (1) establishment of genetic populations with a series of progenies derived from two parents, such as F_2 population, backcross population, doubled haploid (DH) population, and recombinant inbred line (RIL) population; (2) analysis of DNA markers with each progeny, and scoring of each allele; and (3) genetic linkage of the markers and the distance between every two markers is calculated. The first molecular genetic map of rice containing 135 markers based on RFLPs was developed at Cornell University in collaboration with the International Rice Research Institute. The map was generated from an *indica* × *japonica* F_2 population. Primary trisomics were used to assign linkage groups to each of the 12 chromosomes. Since then, many genetic maps have been developed based on either temporary populations (e.g., F_2 and backcross populations) or permanent populations (e.g., DH and RIL populations).

The availability of comprehensive molecular maps in rice has opened a new avenue to tag major genes governing simply inherited agronomic traits and to dissect complex quantitative traits into QTL with molecular markers. Many methods have been developed to dissect complex traits. The simplest method is one marker analysis, that is to analyze the trait value differences between groups of individuals differing for a particular marker. No linkage map is needed in this case. Another commonly used method is interval mapping method in which a maximum likelihood method is used to test the effect of a genomic position within a chromosome interval (two adjacent markers). The disadvantage of interval mapping is its inability to take into account the effects on a trait of multiple QTLs. The other method, composite interval mapping, can resolve this problem and is robust in detecting linked QTLs on the same chromosome (*see* **Genome Mapping**).

For QTL mapping, permanent populations such as DH and RI populations are generally used, because the homozygous nature of each line in these kinds of populations allows carrying out experiments with replication and in different environments. For an F_2 population, the additive effects (A) and dominance effects (D), and percent of total variance can be estimated for each QTL. For a permanent population, dominance effects cannot be estimated because of the homozygosity of each locus. As in the traditional quantitative genetics, if the phenotypic traits are measured across different environments, the QTL × environment interaction can be dissected. Also, marker and marker interaction, referred to as epistasis (or epistatic effects), will be useful in interpreting the variation in some of the measured phenotypes.

From QTL to Gene

Markers are not genes in the classical sense; they often do not have biological function, but they are better thought of as constant landmarks in the genome. However, it is possible to clone the functional gene at a specific QTL without knowledge of its product. The approach to clone the QTL which has been mapped on a specific location of a chromosome is map-based cloning or positional cloning. This strategy is also applicable in cloning major genes whose map positions are known.

Three steps are necessary to carry out this strategy (Figure 1). First, finely mapping the target gene or QTL to as small as possible marker intervals using high-density genetic linkage map. Second, isolating the target chromosomal region containing the gene/QTL of interest by using the flank molecular marker to select the bacterial artificial chromosome (BAC) and yeast artificial chromosome (YAC) libraries. Third, identify the candidate functional gene by subcloning the target region and proof of its identity by mutant complementation with the target gene. High-density genetic linkage maps, good development of BAC and YAC libraries, well-established transformation techniques, and availability of the whole genomic sequence of rice has highly facilitated the isolation of rice genes.

For cloning the QTLs, the construction of special genetic stocks such as near isogenic lines or substitution lines can be used to finely map the putative QTLs as Mendelian factors with high reliability. There are about eight rice genes and QTLs cloned at present based on the map-based cloning strategy (Table 2).

Comparative Genomic Mapping

The development of molecular genetic maps of different cereals using a common set of DNA clones has facilitated comparative mapping among several cereal crops. The implication that knowledge gained from rice will aid in the improvement of other grass species gives an impetus to the studies in comparative mapping. Comparative mapping indicates that there are homoeologous relationships among the genomes of various crop plants. Comparative genome mapping in rice, maize, wheat, barley, sorghum, foxtail millet, and sugarcane demonstrates that gene content and order are highly conserved at both the map and megabase level between different species within the grass family, but the amount and organization of repetitive sequences have diverged

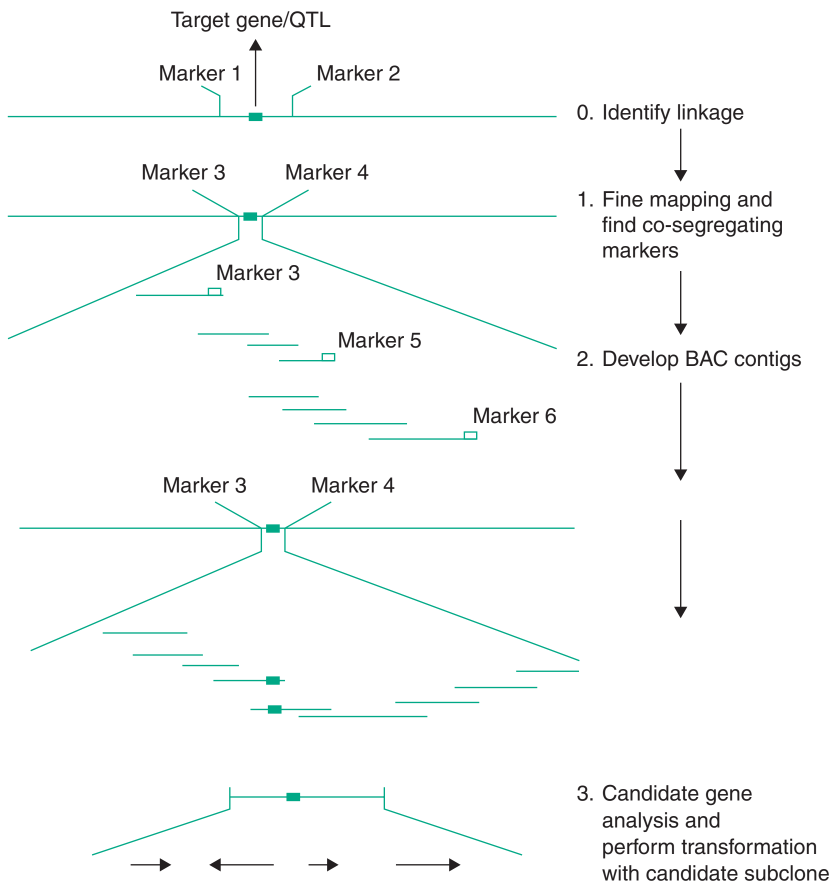

Figure 1 Principal steps for map-based cloning.

Table 2 Genes and QTLs cloned by map-based strategy in rice

Trait	*Gene*	*Biochemical function*
Resistance to blight	*Xa21*	Leucine-rich repeat (LRR) motif and a serine–threonine kinase
Resistance to blight	*Xa1*	LRR-nucleotide binding site (NBS) type of protein
Resistance to blast	*Pi-b*	LRR-NBS type of protein
Resistance to blast	*Pi-ta*	LRR-NBS type of protein
Tiller number	*moc1*	Plant-specific GRAS family protein
Flowering time	*Hd1 (QTL) Se1*	Transcription factor, Constans-like
Flowering time	*Hd6 (QTL) CK2*	Protein kinase
Flowering time	*Hd3a (QTL)*	Unknown

considerably. Microsynteny analysis using the rice YAC library clones of several hundred kilobases has also revealed remarkable similarities in marker order between rice and barley or wheat.

Comparative mapping allows prediction of the presence and location of orthologous loci in other species according to gene location in rice, which accelerates map-based cloning of orthologous genes. The availability of the whole genome sequence of rice has been of great help in other cereals for the discovery and cloning of the orthologous genes or QTLs. The progress in comparative mapping allows comparison of the QTL intervals for similar traits in different crop species. Similarly, the results indicate that the QTL locations are convergent in different cereal species for the same traits. Comparative mapping for domestication-related traits has revealed co-evolution among different cereal crops.

Progress in Rice Genetics

Recent studies show that some important characters in rice are controlled by loci having a major effect on phenotype, but most agronomically important traits

such as yield, quality, and tolerance to abiotic and biotic stresses are quantitative in nature. Here, the current understanding of the genetic basis for the traits of agronomic importance is introduced and major gene tagging (Table 3), QTL analysis (Table 4), and gene cloning and expression (Table 2) underlying the traits of importance are also presented.

Agronomic Traits

Yield and yield-related traits Yield is the most important trait for any rice variety, and thus becomes a major objective in rice breeding programs. Breeding rice with high yield potential is always a dream of rice breeders. Yield and yield-related traits – such as tillers per plant, grains per panicle, and grain weight – are very complex traits with low heritabilities. These traits are controlled by a set of QTLs, each QTL explaining only a few percent of the total variance. However, it seems that some interrelated traits are clustered together on chromosomes 1, 2, 4, and 5 (Table 4). The most useful QTL alleles are distributed among different rice materials. The most significant advance in QTL mapping for rice yield comes from the finding that QTLs from unadapted germ plasm or wild species can enhance the grain yield of cultivated rice. Two yield-enhancing loci, *yld1* (RM5) and *yld2* (RG256), located on chromosomes 1 and 2 of *Oryza. rufipogon* (common wild rice) have been identified, which are capable of improving the yield of modern rice cultivars. This finding is also applicable for identifying valuable QTLs for other traits from unadapted germ plasm so as to widen genetic diversity. Tillering in rice is an important agronomic trait for grain production. A major gene-controlling tiller number, *moc1*, has been cloned by map-based strategy and candidate gene analysis from a spontaneous *monoculm 1* mutant that has only one main culm without any tillers (Table 2).

Plant height Plant height is important in breeding short-strawed, lodging-resistant cultivars in rice. The successful development of a high-yielding semidwarf variety of rice, IR8, based on the recessive gene, *sd1*, led to the so-called rice "Green Revolution" in the 1960s. Both qualitative and quantitative inheritance of plant height have been documented. More than 60 major genes for plant height have been identified by the analysis of naturally occurring variation and the semidwarfing and dwarfing mutants. Two major genes for semidwarfism, *sd1* and *sdg*, have been mapped on chromosmes 1 and 5, respectively (Table 3). Eleven major genes for dwarfism have also been identified and mapped on rice chromosomes (Table 3). Similarly, results from QTL mapping indicate that QTLs controlling plant height distribute on all 12 chromosomes (Table 4). One major finding is that for each previously identified dwarfing or semidwarfing gene, at least one QTL has been mapped to its close proximity. This result supports the hypothesis that QTLs and major genes are different alleles of the same loci. The concept is useful in developing map-based cloning of QTLs. The green revolution gene, the semidwarf gene *sd1*, has been cloned with the candidate gene approach, and found to encode gibberellin 20 oxidase-2 (*GA20ox-2*), catalyzing the conversion of GA53 to GA20.

Heading date Heading date (HD) is a major determinant of the regional and seasonal adaptation of rice varieties, so the control of HD is an important objective in rice breeding. HD of rice is basically determined by three factors: duration of the basic vegetative growth (BVG), photoperiod sensitivity (PS), and temperature sensitivity (TS). Several genes are involved in controlling the first two factors. BVG is controlled by two or three genes. A major gene, *EF-1*, controlling the duration of BVG, is located on chromosome 10. PS is also controlled by several genes including *Se1*, *Se3*, *Se4*, *Se5*, *Se6*, *Se7*, *E1*, *E2*, *E3*, and *PS* (Table 3). Attempts to identify QTLs conferring HD have been carried out by many researchers. The QTLs distribute among all the chromosomes except 5 (Table 4). It seems that different rice genotype possesses different major genes for HD, so that the QTLs detected with large effects also differ in different genetic populations. That the populations derived from Lemont/Teqing, 9024/LH422, and Zhaiyeqing 8/Jingxi 17 have the same QTL on chromosome 8 explains more than 35% of the total variation. The population derived from Lemont/Teqing has anther QTL with large effects (44.7%) on chromosome 3. While in the F_2 population derived from the cross between the japonica variety, Nipponbare, and the indica variety, Kasalath, the major QTL (*Hd1*) with large effects is on chromosome 6. Using several types of progeny derived from Nipponbare/Kasalath, a total of 15 QTLs has been identified for HD (Table 4). Among these 15 QTLs, *Hd1*, *Hd2*, *Hd3a*, *Hd3b*, *Hd4*, *Hd5*, and *Hd9* have been mapped as single Mendelian factors. Three QTLs – *Hd1*, *Hd6*, and *Hd3a* – have been recently cloned by using positional cloning strategy (Table 2). The QTL *Hd1* on chromosome 6 is identical with *Se1* gene which is known as major photosensitive gene, and is closely related to the *Arabidopsis* flowering-time gene, *CONSTANS*. A minor QTL, *Hd6*, involved in PS can be dissected as a Mendelian factor using the advanced backcross

strategy. The cloned gene encodes the α-subunit of protein kinase CK2, but does not correspond to any of the genes identified by mutant analysis in *Arabidopsis* with a role in controlling flowering time. The QTL, *Hd3a*, is an ortholog of the *Arabidopsis* flowering-time gene *FT* which promotes transition to flowering downstream of *Hd1* under short-day conditions.

Disease and Insect Resistance

Resistance to disease There are two major types of disease resistance to plant pathogens, i.e., vertical (qualitative or complete) resistance and horizontal (quantitative or partial) resistance, both have long been recognized as a result of interactions between plant hosts and their pathogens. Vertical resistance in many plant host–pathogen relations is hypersensitive, race specific, and governed by interactions between avirulence genes in pathogens and resistance genes in plant hosts. Horizontal resistance is quantitative, presumably nonrace specific, and controlled by polygenes.

Because of the use of different genetic populations and different pathogen races in QTL mapping, the detected QTLs differ in number and effects in different studies. Even with the same population, different QTLs would result from different pathogen races used. No QTL can confer resistance to all the

pathogen races. Some of the identified QTLs locate in the region where the major genes lie.

According to the protein sequences corresponding to the cloned plant resistance genes, a large number of resistance genes display similar characteristic domains such as a nucleotide binding site and a leucine-rich repeat motif. Candidate gene fragments which involve in both recognition reaction (nucleotide binding site motif, called resistance gene analog marker) and general plant defense (putative defense response) are used as molecular markers to test for association with resistance to rice diseases. When co-localization is observed between the resistance gene analog and a putative resistance locus, the resistance gene analog markers can be assigned to the resistance gene locus and used to further identify the resistance gene. Clustering of these candidate genes in the rice genome has been observed at several chromosomal regions. Some of the clusters locate in regions where QTL associated with partial resistance to rice blast and bacterial blight are known to lie.

Among the diseases, resistance to bacterial blight, caused by *Xanthomonas oryzae* pv. *oryzae* (*Xoo*), has received detailed studies, because bacterial blight is one of the most serious rice diseases in Asia. Currently, more than 26 genes responsible for resistance to bacterial blight have been isolated, 13 of which (*Xa1*, *Xa2*, *Xa3*, *Xa4*, *Xa5*, *Xa7*, *Xa10*, *Xa13*, *Xa21*, *Xa 22*(*t*), *Xa23*(*t*), *Xa25*(*t*), and *Xa26*(*t*)) have been mapped on chromosomes 4, 5, 6, 8, 11, and 12 (Table 3). Three bacterial blight resistance genes (*Xa4*, *Xa5*, and *Xa13*) have been physically mapped, which will facilitate the isolation of the target genes. So far, two bacterial blight resistance genes, *Xa21* and *Xa1*, have been cloned via map-based strategy. The sequence of the predicted protein of *Xa21* carries both a leucine-rich repeat motif and a serine–threonine kinase-like domain, suggesting a role in an intracellular defense response. The deduced amino acid sequence of the *Xa1* gene product contains nucleotide binding sites and a new type of leucine-rich repeat, indicating that *Xa1* is a member of the NBS-LRR class of plant resistance genes but is quite different from *Xa21*.

Resistance to another disease, the blast fungus (*Pyricularia grisea*), has also received scrutiny. The genetic behavior of resistance to blast is very complex. It is genetically controlled by both major genes and QTLs. So far, more than 40 major resistance genes have been identified even though some of them are identical or allelic (Table 3). Some of the major genes have been tagged with molecular markers, and many of them tend to be clustered at particular chromosomal regions, such as those on chromosomes 6, 11, and 12 (Table 3). Two major resistance genes, *Pi-b* and *Pi-ta*,

have recently been cloned with the map-based cloning strategy. Both *Pi-b* and *Pi-ta* encode predicted nucleotide-binding-site-type proteins that are characteristic of products of major resistance genes. There are some QTLs conferring resistance to different races of blast. QTL mapping studies have permitted identifying some new major genes and QTLs as well. None of the major genes or QTLs mapped were found to confer resistance to all races. Inoculating different races of blast fungus, especially new races, can sometimes identify additional resistance genes to those previously reported.

Resistance to insects Brown planthoppers, white-backed planthoppers, stem borers, gall midges, etc., are major insect pests of the rice crop in Asia. Investigations on resistance to insect pests are relatively more recent when compared to those on disease resistance. Rice resistance to insects is most often inherited as a quantitative trait. Some major genes for resistance to brown planthopper, *Bph1*, *bph2*, *Bph10*, etc., have been tagged with RFLP and RAPD markers and mapped on chromosome 12. Gall midge (*Orseolia oryzae* Wood-Mason) is a major dipteran pest of rice. Tolerance to gall midge has also received much genetic study. Seven major genes responsible for gall midge resistance (*Gm1*, *Gm2*, *gm3*, *Gm4*, *Gm5*, *Gm6*(*t*), and *Gm7*(*t*)) have been tagged. Wild rice has valuable genes for resistance to various pests, and the populations derived from cultivated and wild rice crosses contribute to the identification of most of the major genes. For example, *Bph12* has been identified from wild rice *Oryza latifolia* and mapped on chromosome 4 with microsatellite marker RM261, and *Bph13*(*t*) has been identified from *Oryza eichingeri* on chromosome 2 between microsatellite RM240 and RM250. The difficulty in trait measurement in the field hinders extensive investigation of QTLs underlying insect resistance. The threshold to declare a QTL for insect resistance is lower than that for other types of study, so that the QTLs identified are less accurate in position and explain a lower percentage of the total variation.

Abiotic Stresses

Tolerance to low temperature Low-temperature stress is common for rice grown in temperate regions and at high elevations in the tropics. Low temperatures dramatically reduce grain yield if the stress coincides with the sensitive period during the reproductive stage of rice by inducing spikelet sterility due to failure of microspore development or a decrease in the number of pollen grains per anther. Studies have been conducted to locate QTLs on chromosome regions responsible for cold tolerance at the booting stage which would affect the floret sterility. The number of QTLs differ in the different populations (Table 4), indicating that useful QTLs are maintained in different rice materials.

Tolerance to submergence Rice is well known for its ability to grow under flooding, but most rice cultivars cannot survive if the plants are completely submerged for more than 7 days. In many genetic studies, this trait appears quantitative, but more careful testing reveals the effect of the major gene, designed *Sub1* in the F_2 population derived from a submergence tolerant indica line, IR40931-26, and a susceptible japonica line, PI543851. The *Sub1* locus is tagged with two RFLP markers, RZ698 and C1232, on chromosome 9. QTL mapping for submergence confirms that the locus at *Sub1* has a large effect on submergence tolerance, while four other QTLs have much smaller effects. High-resolution mapping of the region surrounding the *Sub1* has been undertaken, serving as the basis for map-based cloning of this important gene.

Tolerance to drought Drought is the major abiotic stress-limiting rice yields in rainfed environments. Tolerance to this abiotic stress is a complex process and is one of the crop genetic improvement's least understood genetic traits. Nevertheless, a few researchers have made significant progress in this aspect from the perspective of molecular marker mapping of components of drought tolerance-related root system parameters, such as root morphology, root penetration ability, osmotic adjustment, and cell membrane stability. Comparison of positions of QTLs across a few mapping populations reveals that there are several common regions associated with deep root morphology traits and root thickness traits, indicating a potential for marker-assisted selection for these traits.

Tolerance to adverse soils Adverse soil conditions hinder rice growth and development, such as high salinity, phosphorus deficiency, high aluminum content, etc. Genetic analysis of rice resistance or tolerance to adverse soil depends on the establishment of simple but quick and relatively accurate identification methods. Rice is sensitive to salinity, which affects one-fifth of irrigated land worldwide. Reducing sodium and chloride uptake into rice while maintaining potassium uptake are characteristics indispensable to aid growth under saline conditions. Genetic control of this trait appears to be quantitative. QTL mapping can dissect this complex physiological trait by

measuring its physiological components, such as Na^+ concentration, Na^+ uptake, K^+ concentration, K^+ uptake, and Na^+/K^+ ratio. The QTLs for these traits have been mapped on chromosomes 1, 4, 6, and 9. Phosphorus deficiency occurs widely in rice soils with a high native phosphorus-fixing capacity, such as in acid soils, acid sulfate soils, and alkaline soils. Only two studies have been conducted on mapping QTLs for the traits responsible for phosphorus deficiency, enabling identification of a major QTL on chromosome 12 flanked by RFLP marker RG9 and RG241. Several other minor QTLs are mapped on chromosomes 1, 2, 3, 4, 6, 9, and 10 (Table 4).

Grain Quality

Cooking and sensory quality The three most important parameters to evaluate the cooking and sensory quality of rice are amylose content (more accurately termed apparent amylose content), gelatinization temperature, and gel consistency. The change of starch viscometric properties during heating and cooling commonly tested with a Rapid Visco Analyzer simulates the cooking process, and serves as an indicator of the eating and cooking characteristics of milled rice and rice flour. Rice with aroma when cooked is often at a premium in many markets.

Amylose content has been found to be primarily controlled by an allelic series at one locus with major effects and by one or more modifier genes with minor effects. Through QTL analysis, amylose content is also reported to be controlled by a major QTL as well as other minor QTLs. This major QTL is at the *Waxy* (*Wx*) locus, which encodes granule-bound starch synthase (GBSS). The QTLs with large effects controlling gel consistency and amylograph characteristics are also at *Wx* locus, though there are many others with minor effects (Table 4).

Gelatinization temperature is a typical qualitative–quantitative trait. One to three genes with several modifiers reportedly control this trait. QTL analysis indicates that gelatinization temperature is controlled mainly by the *alk* gene loosely linked ($\sim$28 cM) with *Wx* on chromosome 6. It is possible that the starch synthase IIa (*SSIIa*) gene is located at the *alk* locus, because *alk*, *SSIIa*, and amylopectin chain length (*acl*(*t*)) are mapped to the same locus (Table 3). In a case where the genetic population was derived from parents with similar gelatinization temperature ("IR64" and "Azucena"), it was found that the *Sbe1* gene locus on chromosome 6 encoding starch branching enzyme I controlled gelatinization temperature.

The aroma of cooked rice contributes to consumer sensory acceptance. Several hundred compounds can be observed in the volatiles of cooked rice, and more than 200 of these have been identified. The aromatic compound 2-acetyl-1-pyrroline is reportedly the primary component of the popcorn-like smell of aromatic rice. The major gene designated as *fgr* has been identified by several researchers on chromosome 8 flanked by RG28 and RM223 by 3.6 and 1.9 cM, respectively (Table 3).

Appearance The appearance of milled rice affects consumer acceptance of the product. Grain size and shape are the most stable properties of a rice cultivar. Some QTL studies have been conducted for grain length, grain width, and grain shape (length/width). Even though the number and effect of QTLs are different in different populations used, a QTL on chromosome 3 has been repeatedly identified for grain length, grain width, and grain shape. Two major QTLs are detected on chromosomes 8 and 12 for the percentage of grain with white core, and one minor QTL is found on chromosome 3 controlling area of white core. White belly seems to be primarily controlled by a major locus on chromosome 5, located in the same genomic region as a major QTL for grain width.

Milling quality The market value of rough rice, in part, reflects the percentage of head rice to total milled rice produced after milling. Milling yield is a complex trait affected by both genetic and environmental factors. A major QTL at the interval between markers RM42 and C734b on chromosome 5 controls brown rice yield, while a major QTL located at the interval of C1087-RZ403 on chromosome 3 controls head rice yield. These two loci are the major QTLs for grain width and grain length, respectively.

Future Prospect

Marker-Assisted Selection

The potential usefulness of molecular markers linked to genes or QTLs is essential to the future success of molecular breeding programs. However, integrating DNA marker technology into conventional rice breeding has not been implemented widely. One reason is possibly due to the high cost of the techniques. The second is that many breeders are not so skillful in accessing the database information, and some are still stubborn to accept new methods and stick to phenotypic selection in the field. Strategy for molecular breeding requires introduction of target genes or QTLs of interest by using molecular biotechniques, including the alien genes of the donor traits from wild rice. Pyramiding more genes and QTLs into one

individual plant through marker-assisted selection is feasible for genes for disease and insect resistance, thus conferring high resistance to diseases and insects. The current development of new types of molecular markers, SNP, particularly those inside the genes, provides unlimited genetic markers for genetic linkage map construction. The quantitative traits can then be dissected into quantitative trait nucleotides (QTN) instead of QTLs by using this kind of genetic marker. Consequently, the SNP in relation to agronomically important traits can also be used in rice conventional or backcross breeding. In the next decade, more rice varieties will be bred successfully and efficiently with marker-assisted selection.

Functional Genomics

Positional cloning strategy has been demonstrated successfully in the cloning of eight genes and QTLs for traits of agronomic importance in rice. This strategy, however, is time, cost, and resource consuming, and fails to clarify the metabolic pathways underlying the phenotypic formation of traits of interest. The biological function of the cloned genes needs further investigation. The availability of whole genome sequence data of rice has emphasized the role of forward genetics, and the immediate may be characterized as an era of functional genomics.

Many artificial mutants have been generated with various approaches, such as the physical and chemical mutagens, AC/DS transposable elements of maize, retrotransposons, and T-DNA insertions. These mutants were previously utilized for forward genetics, and now are very popular for reverse genetics by providing the necessary link between structural or sequence data and gene functions. High throughput of gene expression analysis on microarrays facilitates quick acquisition of genes or expressed sequence tags in relation to phenotypic expression of different agronomic traits, and makes possible identification of metabolic pathways. This technology improves the methodologies in gene cloning with high efficiency. The early decades in twenty-first century will witness more genes cloned and gene functions clarified.

Breeding

Qingyao Shu and Dianxing Wu, Zhejiang University, Hangzhou, People's Republic of China

It is difficult to trace man's earliest efforts to improve the rice plant. However, long before the advent of science, man undoubtedly had made good use of natural variation from spontaneous mutations and natural hybridizations. Susrutha (*c*., 1000 BC) in his Ayurvedic *Materia Medica* recognized the differences among rice cultivated in India and separated them into groups based upon their growth duration, water requirements, and nutritional values. Chinese classics show that Emperor Wen Ti of the Wei Dynasty (AD 186–226) discussed with his cabinet about quality rice having strong and fragrant aroma. Another Emperor, K'ang His (1662–1723) of the Ching Dynasty, selected an early maturing and aromatic mutant for a crop of rice grown in the Imperial Garden that later became the main staple of his household. The new strain was named Imperial Rice. The large-scale introduction, testing, and distribution of the early maturing Champa rice in central and east China during the eleventh century marked the first massive government-sponsored efforts to utilize efficient and productive genotypes.

Modern rice breeding is a major component of the Green Revolution which resulted in remarkable increases in rice production due to large-scale adoption of high-yielding semidwarf varieties. The development of hybrid rice further increased rice yield by 15–20% beyond the level of semidwarf rice varieties in China, and use of hybrid rice has recently been expanding in other countries. Modern varieties have had a dramatic impact on yield increases in rice production. World rice production doubled in a 25-year period, from 257 million ton (Mt) in 1965 to 520 Mt in 1990. However, to keep pace with an alarming rate of increase in the rice-consuming population, breeding of new rice varieties is an important and indispensable way to further enhance rice yield potential and stability, and adaptability to adverse soil and climatic conditions. New varieties will enable people to produce more rice from less land, with less water, less labor, and by using less pesticide. Recent breakthroughs in plant molecular biology and biotechnology have continued to revolutionize the methodology and technology of rice breeding, and will enable rice breeders to develop new varieties more efficiently.

Breeding for High Yield and Wide Adaptability

Yield enhancement has long been one of the most important objectives in rice breeding. Efforts to combine a high yield with season-independent adaptability were initiated in subtropical Taiwan during the 1920s. Taichung 65 and other "Ponlai" series varieties represented a distinguished group (kêng) that is insensitive to changes in photoperiod and temperature, early maturing, nitrogen responsive, and high yielding. Ponlai varieties could be planted in both the first (spring) and second (summer) season of Taiwan and allow intensive multiple cropping between the rice crops. From a cross between a tall indica variety and the semidwarf Dee-geo-woo-gen (DGWG), the early maturity semidwarf variety Taichung Native 1 (TN1) was developed in 1956. It responded much better to heavy nitrogen fertilization and outyielded the popular Ponlai varieties. TN1 was widely used in the hybridization programs of India and by International Rice Research Institute (IRRI), the Philippines. Soon after IRRI began its research activities in 1962, the primary breeding objective was to develop high-yielding, short-and-stiff-culmed, photoperiod-insensitive rice varieties that would resist lodging under heavy fertilization and would have wide adaptability in tropical areas. The famous semidwarf IR8, regarded as the most important rice variety leading to the Green Revolution, was bred from the cross of Peta/DGWG in 1966. From different country programs in tropical Asia and elsewhere, a large number of semidwarf varieties have been developed since 1968, either using TN1 or IR8 as semidwarfing parent. The more notable varieties are Jaya, Padma, Bala, Ratna, Sona, Cauvery, and Annapurna of India; RD1 and RD2 of Thailand; Meheran 69 of Pakistan; Chandina and Mala of Bangladesh; and CICA-4 and CICA-6 of Colombia.

Efforts to develop high-yielding semidwarfs on the China mainland began in the mid-1950s.

Ai-chio-nan-te and Chen-chu-ai were two of the initial releases in 1959. Ai-chio-nan-te (Ai-jiao-nan-te), Chen-chu-ai, Kwang-chang-ai (Guang-chang ai), Chiang-nan-ai (Chang-nan-ai), and Nung-k'en (Nong-ken) 58 were the principal varieties grown during the mid-1960s in central and south China, and they gave rise to improved semidwarfs or "kêng" types such as Ai-nan-tsao 1 (Ai-nan-zao 1) and Hu-hsuan 17 (Hu-xuan 17). The development of early maturing semidwarfs (100 days or less) such as Ai-nan-tsao 1 and its derivatives made triple cropping possible in Guangdong Province and double cropping in Shanghai-Nanjing area. The above semidwarfs have the same recessive gene for short stature as in DGWG.

Breeding for Stable Yield

After the marked jump in yield potential was attained in the late 1960s, the next problem was to stabilize the high yield level in the face of intensified disease and insect pest pressure, which cause the loss of more than 200 Mt of rice each year. Rice fields in irrigated areas of the Asian tropics were ravaged by diseases and insects after increased nitrogen fertilization, dense planting, multiple cropping, and continuous planting of a few high-yielding varieties. Associated with the dominance of a few varieties of similar genetic backgrounds, a new or hitherto obscure biotype of a genetically plastic pest may appear in quantity, and the resistance in the major varieties breaks down. Successful progress has been made in transferring a major gene or a gene complex for resistance to specific diseases and pests into the high-yielding backgrounds. The transfer of the desired gene or genes was made by way of single or multiple crosses or a combination of them. The resistance genes for bacterial blight, blast, grassy stunt, tungro, green leafhopper, and brown plant hopper have all been incorporated into improved varieties. Among environmental factors affecting yield stability, resistance to drought and tolerance to submergence in flood waters are also essential to stabilize crop yields during seasons of erratic precipitation.

Breeding for Grain Quality and Improved Nutrition

The consumer prefers rice with a clear (translucent) endosperm and pays a premium price for it. Grains with chalkiness in the endosperm, caused by loose packing of the starch and protein particles, break more easily than translucent grain during milling, thus greatly reducing the market value. The opaque areas are known as white belly, white center, or white back, depending on the location within the endosperm. For evaluation of breeding materials, it is most convenient to group them together as white belly rather than to individually rate each type. A few varieties have almost totally opaque endosperm. Other varieties are translucent or have only minute traces of white belly. The presence and degree of white belly are partially under genetic control although certain environmental factors (high temperature immediately after flowering) markedly affect their expression.

Preferences for grain length and shape vary among countries and marketing areas. Width and thickness, or shape, are less variable and less important than length, although the highest-quality markets usually demand a slender to medium width. Length and shape of grain are independently inherited and can be combined as desired with the possible exception of the extra long and bold characters. Furthermore, there are no barriers to recombination of any expression of grain length and shape with other quality traits, or with plant type, dormancy, or maturity period. Nevertheless, grain size and shape are relatively difficult traits to handle. The most important consideration is for the breeder to know which grain types are desired in the markets he serves and to stringently reject all segregates that do not meet those requirements. Improved semidwarf plant types with essentially all possible combinations of grain shape and length are available as parents in the germ plasm. Grain shape and length are quantitatively inherited. Grain size is highly heritable in most environments although low temperature after flowering can slightly reduce grain length. Despite the apparent complexity of their inheritance, grain length and shape appear to be fixed exceptionally early in the segregating generations. Preliminary selection for grain appearance can be based on visual evaluation in the field and laboratory based on examination of rough rice, and supplemented later with more accurate measurements on milled rice.

Careful evaluation of milling quality, particularly percentage of head rice, is critical in all rice breeding programs. Unfortunately, there is no simple, accurate technique to directly measure milling quality in segregating generations. It is imperative to run at least one evaluation of milling quality, preferably more, in a well-adjusted commercial mill before releasing a new variety.

Amylose is the linear fraction of starch in the nonglutinous varieties. Amylopectin, the branched fraction, makes up the remainder of the starch. Amylose content has a major influence on the characteristics of cooked milled rice, including cohesiveness,

tenderness, color, and gloss of cooked rice. Rice varieties are grouped on the basis of their amylose content into waxy amylose (1–2%), low amylose (8–20%), intermediate amylose (21–25%), and high amylose (more than 25%). Cooked glutinous or waxy rice is very moist, sticky, and glossy, and is the staple food in a few small areas in Asia. The nonwaxy varieties make up the bulk of the world's rice, ranging from 8% to 37% in amylose content. Low-amylose varieties are moist, sticky, and glossy when cooked, and readily split and disintegrate when overcooked. Rice with a high-amylose content such as IR8 cook dry and fluffy but become hard upon cooling. Intermediate types such as IR64 have the fluffiness of high-amylose types but retain a soft texture when cool. Japonica varieties tend to have low-amylose content and to be sticky when cooked. Indica varieties vary widely in amylose content according to regional quality preferences. High- and low-amylose types appear to differ by control of a single gene. The heterozygote has intermediate amylose but this cannot be stabilized. If intermediate amylose content is desired, one or both parents must be intermediate. Amylose content is partly modified by environment in largely unknown ways. High temperature during grain ripening lowers amylose content. Some varieties can vary as much as 6% in content from season to season.

Varietal differences in gel consistency exist among varieties of similar high-amylose content. Gel consistency of rice with less than 24% amylose is usually soft. The gel consistency test was developed to complement the amylose test in breeding programs for rice quality. Gelatinization temperature is partly associated with the amylose content of the starch, the major determinant of cooking behavior.

Milled rice has excellent digestibility and good protein quality, but the gross protein content (7–9%) is rather low for nutrition of children. Efforts have been made at IRRI and in China to increase the brown rice protein. High protein content appears to correlate with low yield in fixed genotypes. The use of protein per seed appears to be a more effective selection criterion than the brown rice protein content of a bulked seed sample of a plant or breeding line. Cultivation, especially use of nitrogen fertilizer, can affect protein content of milled rice to a great extent. However, high protein content is not always a preferred character, because it is very often negatively related to low eating quality.

Fragrance of cooked rice is preferred in many areas. Several chemical constituents are important to the aroma of cooked rice. However, 2-acetyl-1-pyrroline (2-AP) is the most important component. Aroma is a recessive trait that is controlled by a single recessive gene. In aromatic rice, all parts except root contain 2-AP, and it could be detected by tasting the associated flavor in individual seeds or assessing the aroma of leaf tissues or grains after either heating in water or reacting with KOH. Therefore, selection of aromatic trait is not much difficult. Improved varieties having the aromatic quality – such as Sabarmati, Pusa 33, PR967-11, and Jasmine 85 – have been developed in South Asia and elsewhere. More recently, molecular markers, such as RM223 and RM42 in Australia, have been developed for this important trait, which may accelerate the breeding of aromatic rice.

Richness in micronutrients – such as Fe, Zn, and Ca – is a very important and desired trait in rice, because micronutrient malnutrition is a common phenomenon in countries with rice as staple food. Breeding of Fe dense rice has been initiated in several countries, but the progress has so far been very limited in conventional rice breeding. However, by using genetic engineering, transgenic rice plants reported with a ferritin gene form *Phaseoulus vulgaris*, and the Fe content was doubled in grains. Apart from increasing the mineral content in rice grains, reduction of antinutrient components is another way to increase the bioavailablity of micronutrients of rice. In this aspect, low-phytin rice might be the best choice, and some prototypic rice lines have been already developed, but their actual usefulness remains to be tested.

Breeding for Overcoming Stress Factors

Productivity in upland, rainfed lowland, and even irrigated rice is limited by inadequate water at certain phases of growth. As much as 90% of the world's rice-growing area is estimated to suffer from drought at critical growth stage. Under upland culture, thick and deep roots and ability to maintain leaf turgor are two of principal traits associated with drought resistance. Under rainfed lowland culture, the ability to maintain leaf water potential is clearly associated with drought resistance although the root system may play a somewhat smaller role. Incorporation of recovery ability from drought is also essential to the rainfed lowland culture.

Tolerance to submergence in flood water is different from tolerance to deep water. The two traits need to be evaluated separately, and specific qualities are needed for rice grown in deep water. To make breeding contribute more to productive and sustainable rainfed lowland rice system, genetic variation has been identified for both broad adaptation across target rainfed lowland environments and specific adaptations to some of the abiotic stress environments, e.g., late season drought, and submergence during vegetative development.

Tolerance to cool temperatures became necessary when population pressure forced farmers to cultivate rice at high elevations in tropical Asia. Good progress in breeding for cold-water tolerance in northern Japan and in California has been attained. Success appears to be attributable to long years of empirical testing and selection, use of diverse germplasm, and development of efficient cultural practices.

Millions of hectares in humid regions of Southeast Asia are left idle or are grown with very low yields because of salinity and abiotic stresses, though the climate is suited for rice production. Mineral deficiencies and toxicities frequently compound the problem of salinity. Rice varieties with partial tolerance to particular abiotic stress, e.g., salinity, alkalinity, iron toxicity or deficiency, zinc deficiency, phosphorus deficiency, manganese and aluminum toxicity, are available in rice germplasm. However, most of these varieties yield poorly and lack resistance to major disease and insects. Progress has been made recently in developing rapid and reliable screening techniques of saline tolerance, identifying and improving tolerant germplasm. Genetic analysis of the tolerance to most soil-related stresses has also been studied in rice, and elite lines have been developed with tolerance to multiple stresses. Many new varieties have been released with enhanced tolerance to such stresses and planted in salt-affected areas.

Breeding for the New Plant Type
